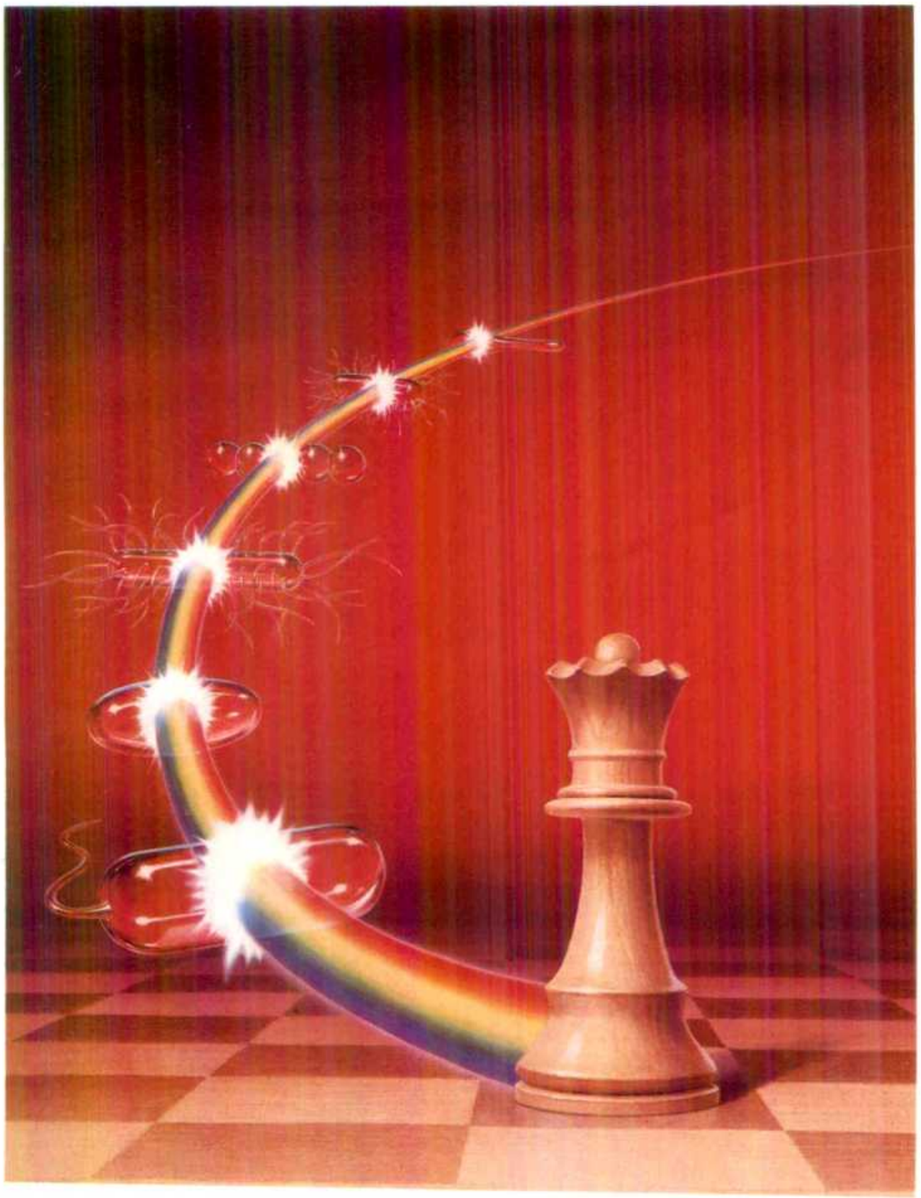
PIPRIL
INTRAMUSCULAR/INTRAVENOUS PIPERACILLIN

Still a key move
in surgical infections



- Proven single agent activity[1-3]
- Broad spectrum cover, including anaerobes.[4] Active against *Strep. faecalis*[5] – unlike cephalosporins, aminoglycosides and metronidazole.
- Highly synergistic with aminoglycosides[6,7]
- Low potential for inducible resistance compared with 'third generation' cephalosporins[8,12]
- Effective concentrations in bile and peritoneal fluid[9,10]
- Well tolerated[11]

Prescribing information. **Indications:** Pipril is a broad spectrum bactericidal penicillin for the treatment and peri-operative prophylaxis of systemic or local infections caused by sensitive organisms. **Dosage:** Adult patients with normal renal function should receive 4-8g daily in divided doses for mild or uncomplicated infections. In serious or life-threatening infections 12-16g daily in divided doses. For peri-operative prophylaxis 2g just prior to surgery followed by at least two doses of 2g at four or six hour intervals. Patients with renal insufficiency may need dosage reduction – see Data Sheet. Children 2 months to 12 years of age: 100-300 mg/kg daily in three to four divided doses. Neonates and infants under two months of age: 100-300 mg/kg daily in two equally divided doses. **Contra-indications:** Penicillin or severe cephalosporin hypersensitivity. **Precautions:** Safety for use in pregnant or lactating women has not yet been established. **Side effects:** Uncommon and typical of injectable penicillins. **Administration:** Pipril is presented as 1g or 2g vials, 4g infusion bottles and 4g infusion packs containing piperacillin as piperacillin sodium. See Data Sheet or package leaflet for full details of preparation and administration. **Product Licence No.** 0095/0073. **Basic NHS Price:** 1g vial £2.98, 2g vial £5.90, 4g infusion bottle £11.66, 4g infusion pack (4g bottle, 50 ml WFI plus needle) £12.43. Further information is available on request.

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state. if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988, **108**: 258–65 or to obtain the leaflet 'Uniform ,Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page· title page, summary, text, acknowledgements, references, tables, legends for illustrations

Title page

The title page should give· (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support, (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, ie 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983, **286**· 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s), title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66 184–6 The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications.* New York: Springer-Verlag 1981: 123–63.

AIMS AND SCOPE

The aim of this journal is to present all aspects of surgical research. Both clinical and laboratory-based work is reported. Communications from surgeons-in-training, who are involved in a period of full-time research, are welcome. The journal publishes original full length articles of high scientific standard, with appropriate trial design and analysis, in fundamental surgical science. Retrospective reviews and short reports of negative results are also included and, occasionally, didactic case reports.
In addition, this journal publishes reviews, selected symposia proceedings, reports of significant meetings, correspondence, and book reviews.
A 'camera-ready' rapid communications section is also included.

Butterworths

1st INTERNATIONAL POSTGRADUATE COURSE IN ENDOCRINE SURGERY
2–7 JULY, 1989 · CAPSIS BEACH HOTEL · CRETE · GREECE

The first International Postgraduate Course in Endocrine Surgery will be arranged in the island of Crete in the newly built luxurious hotel Capsis Beach, located in a beautiful peninsula with sandy beaches and rocky caves with crystal clear waters. Excellent recreational and entertainment facilities guarantee an unforgettable stay for all participants and their families.
The Course is open to all physicians, especially general surgeons, interested in Endocrine Surgery.

FACULTY AND MAIN LECTURERS

Orlo H. Clark, M.D., San Fransisco, USA
Jon van Heerden, M.D., Rochester, MN, USA
Sten Lennquist, M.D., Linköping, Sweden
Dimitros A. Linos, M.D., Athens, Athens
Charles Proye, M.D., Lille, France
Hans Röher, M.D., Düsseldorf, West Germany
Norman Thompson, M.D., Ann Arbor, MI, USA
Malcolm Wheeler, M.D., Cardiff, UK

A number of other invited distinguished speakers will further enrich the scientific program.

MAIN TOPICS

The thyroid nodule – diagnosis and management · *Hyperthyroidism* – a surgical disease? · *Thyroid carcinoma* – controversies in treatment, surgical strategy · *Hyperparathyroidism* – diagnosis, indications for treatment and surgical strategy · *Adrenal tumors* – management of incidentaloma, surgical strategy · *Gastrointestinal endocrine tumors* – islet-cell tumors of the pancreas, carcinoid tumors · Workshops in surgical technique with video sessions

REGISTRATION FEE

US $300, covering participation in all educational activities, hand-out material and participation in cocktail and barbecue parties.

ACCOMMODATION FEE (PER PERSON, DAILY ON HALF BOARD)

In single room US $76. In double room US $60–70. Additional twin beds: 30% reduction. Children: Below 6 free, 6–12 50% reduction.

TRAVELLING

Charter flights can be arranged from Frankfurt directly to Heraklion (prices depending on distribution of participants).

APPLICATION

Deadline for application is January 10, 1989. The number of participants is strictly limited and those who applicate first will be first accepted.
Further information and application forms can be requested from: *Secretariat of the 1st International Postgraduate Course in Endocrine Surgery,* c/o D. Linos, 110 Vasilissis, Sophias Avenue, GR 11, 527 Athens, Greece. Tel: 1-777 1023.

Sten Lennquist
Chairman of the organizing committee
(Address: University Hospital,
S-581 85 Linköping, Sweden, tel: 13-19 35 54

Dimitrios Linos
Chairman of the local committee
(Address: see above)

SECOND INTERNATIONAL CONFERENCE ON MELANOMA

Venice (Italy) – October 16–19, 1989

The **Second International Conference on Melanoma** will follow the scientific lines of the First International Conference held in Venice in 1985. During the last four years a large body of new information on melanoma has been made available by many laboratories and clinical Institutions all over the world. New epidemiological studies on melanoma, new data on its biological behaviour, new information on its immunological aspects, together with fresh results from clinical trials on treatment and from new prospective researches in immunotherapy will be at the center of the discussions by the innumerable scientists who are expected to be present in Venice. The originality of this Conference, like the previous one, is the wide range of different disciplines represented in most sessions and the structure of the meeting, although slightly modified from the previous one, was planned with the aim of meeting the requirements of a true interdisciplinary exchange of experience.

President: Umberto Veronesi, M.D.

Chairman Scientific Programme Committee and Secretary General: Natale Cascinelli, M.D.

Official language: English

Congress Fees:

Pre-registration:	U.S.$ 400 (before March 31st, 1989)
Late registration:	U.S.$ 500 (after March 31st, 1989)
Accompanying person(s):	U.S.$ 200/250

Further information:

General Secretariat, Second International Conference on Melanoma, c/o Istituto Nazionale Tumori, Via G. Venezian 1, 20133 MILANO (Italy). Tel: (02) 2663992 or 2390275. Telex: 333290 TUMIST I

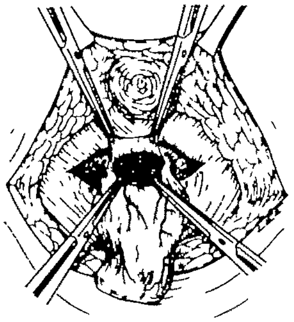
MANAGEMENT OF ABDOMINAL HERNIAS

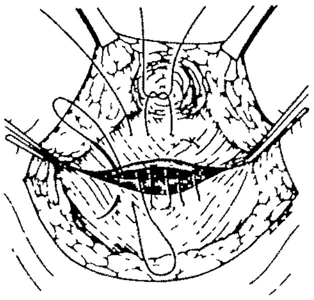
H Brendan Devlin MA MD MCh (Dublin) FRCS(England) FRCS(Ireland) FACS
Consultant Surgeon, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

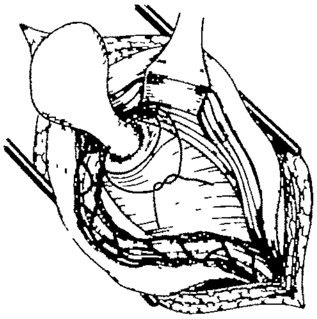
- ★ **the author is a leading authority on hernia management**
- ★ **extensively illustrated with high quality line drawings, half-tones and colour photographs.**

Management of Abdominal Hernias is the most comprehensive work to date on the subject. In this exhaustive volume the author discusses the historical background to hernia management and its influence on current practice.

The basic sciences and operative technique of hernia surgery are dealt with in practical terms and guidance on complications and postoperative care is supported by new data based on long term studies.







"This book is beautifully produced, clearly written and profusely illustrated, mainly by excellent line drawings. It would be of considerable value to the surgeon in training (who, in this country, is called upon to do the majority of this type of surgery) but it would also be read with interest by his Chief."

British Journal of Surgical Practice

"The anatomy of the abdominal wall is excellently set out and clearly described and I would recommend all surgeons in training, particularly at senior house officer level, to read it.

"This is a very readable and enjoyable book. It is not directed at any particular grade of surgeon but will inform and enlighten the majority of those who read it."

British Journal of Hospital Medicine

Concise contents: Preface · General introduction and history of hernia surgery · Essential anatomy of the abdominal wall · Epidemiology and aetiology of primary hernias in adults · Logistics and economics of hernia repair · Principles in hernia surgery · Anaesthesia · Complications of hernia in general · Groin hernias in babies and children · Umbilical hernia: operation in babies and children · Diagnosis of a lump in the groin in the adult · Inguinal hernia in adults · Femoral hernia · Extraperitoneal or preperitoneal repair of groin hernias using prosthetic reinforcement · Umbilical hernia in adults · Epigastric hernia · Obturator hernia, lumbar hernia, sciatic hernia, supravesical hernia · Spigelian hernia · Incisional hernia (excluding parastomal hernia) · Parastomal hernia · Complications of hernia repair · Epilogue and general conclusions · Biographical notes · References and further reading · Index

Surgeons and computers

In the 1980s computers have been characterized not so much by increased cleverness as by shrinking size, increased speed, enormously increased memory and dramatically falling prices. These changes have greatly enlarged the usefulness of computers in medicine and in the business of providing health care. However while surgeons cannot claim to be ignorant of the revolution occurring around them, they have, in general, shown themselves to be uninterested or incapable of exploiting the change. Indeed this journal receives very few papers describing the harnessing of computer power for clinical benefit. It is understandable that surgeons seem to show reluctance in this area; by nature they prefer to deal with diseases that they can see and handle yet nothing could be more covert than the anatomy of computers, nothing more enigmatic than their physiology. Surgeons have no training that helps them to understand these machines and most have had little or no interactive contact with them. The resulting gulf is not entirely the surgeon's fault. The interfaces between computers and humans are too often clumsy and unsympathetic and the exploitation of the computer is too often left to sycophants who can only chatter in jargon.

Early attempts at bringing computers into the area of clinical diagnosis were over-ambitious and, in its non-clinical uses, the computer was and still is perceived largely as a weapon for meddlesome managers. The time must surely have come for surgeons to put away their understandable anxieties and scepticism and instead contribute to relevant and imaginative applications for the new computers. Starts already made include the computerized follow-up of patients, the computer surveying the answers on questionnaires and the results of tests that it has arranged, thus identifying those patients in need of closer clinical scrutiny. In image processing computers may soon be able to provide more than just neater pictures, they will be able to store them digitally and retrieve and transmit them instantly, and so provide a limited interpretive service[1,2]. In the processing and storage of all routine clinical information computers will predominate, and perhaps the mishap of the lost result and the overlooked abnormal result will become a thing of the past. 'Smart cards' the size of credit cards are already capable of holding 20 million bits of information such that patients might carry their own medical records[3]. As the trend to early diagnosis and preventive medicine takes hold, computers will be able to take over some of the mundane questionnaire functions involved.

Even in the difficult area of clinical diagnosis computers have already shown their use, as in the benefits described by Adams *et al.* for a system analysing acute abdominal pain[4]. The application of that system halved the negative laparotomy rate and reduced the mortality rate. Major reservations about the role of computers in diagnosis still exist and are discussed by Sutton in this issue (pp. 82–85). Computers are already central to the anaesthetic and intensive-care monitoring of vital signs and might equally be used to control the administration of drugs and the accurate prescription of drug regimens and parenteral nutrition. The involvement of computers in management already reaches beyond simple audit and data storage to using that data for 'what if...?' exercises in prediction. Surgeons are already prominent in the computerizing of audit but, as in other areas where clinical and managerial functions overlap, certain ideological and philosophical changes will be required if the product of computerized audit is to be used to improve care. Even our concepts of 'clinical freedom' may have to change if audit shows our free practices to be harmful[5]. Where audit points up a need for re-education, the computer will help. Free and easy access to comprehensive medical databases through any hospital computer terminal ought to be normal practice, but the surgeon will only demand such access when he realizes the need and can manipulate the computer. In the not too distant future most medical journals, including this one, will be available through the medium of the computer screen.

Even in his most fiercely protected lair, the operating theatre, the surgeon must expect the computer to intrude. Recent government reports[6,7] have shown that in the UK the average use of available prime weekday theatre time is only 60 per cent. Computers can solve the problem of how to reduce this waste, just as long ago they solved the difficulties of filling the seats on airliners. Within the next few years the new generation of computer-literate young people brought up with computer studies at school and microcomputers at home will be qualifying in medicine. If we are not to

0007–1323/89/010001–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

have two cultures in the surgical team their seniors must be prepared to educate themselves about the general principles of computers. They will not need to be able to type or to understand most of the jargon, but they will need to set aside any phobias they have about screen and keyboard. They will certainly not need to know anything about programming. They will need only to understand the principles, the powers and the limitations of computers and data transmission systems. Readable explanatory books are available[8] but more pragmatic and comprehensible material needs to be produced. In the end, though, all that is needed is an open mind.

Lower gastrointestinal bleeding

Over the last decade, there has been a major shift of emphasis with regard to lower gastrointestinal bleeding. The recognition of angiodysplasia as a not uncommon cause of haemorrhage has led us to reassess much of our earlier teaching. In addition to the other common cause of bleeding, namely diverticular disease, acute bleeding may also occur in inflammatory bowel disease, radiation enteritis, and ischaemic colitis, and may originate from vascular tumours. From a clinical viewpoint, bleeding from the distal small bowel, most often from a Meckel's diverticulum, cannot be distiguished from bleeding from the proximal colon.

Angiodysplasia has come to the fore over the last decade as a major cause of gastrointestinal bleeding. In a Hammersmith series of 67 patients with this problem, 13 per cent presented with an initial acute bleed, 46 per cent with recurrent acute bleeding and 33 per cent with chronic bleeding (usually presenting as anaemia). In 7 per cent of patients, angiodysplasia was an incidental finding on angiography and occurred in association with other lesions[1]. Case selection is partly responsible for the fact that angiodysplasia was by far the commonest cause of colonic bleeding seen at the Hammersmith Hospital, being nearly ten times as common as acute diverticular bleeding. It was responsible for 74 per cent of all cases of red bleeding per rectum, 18 per cent of all cases of 'melaena' and 49 per cent of all cases presenting with anaemia secondary to colonic bleeding. Clearly this pattern of disease reflects the experience of the unit to which patients are referred for angiography in the investigation of bleeding, and does not represent the true incidence of angiodysplasia as a cause of bleeding in the population. When diagnosed by angiography, angiodysplasia is almost always in the caecum or ascending colon. Although a higher incidence of angiodysplastic lesions is seen in the left colon at colonscopy, these rarely show on angiography and do not often cause significant bleeding. Angiodysplasia may be diagnosed either endoscopically or by angiography, though the former may be difficult during an acute bleeding episode. However, most such episodes stop spontaneously, so that this is not a practical difficulty.

If angiodysplasia is diagnosed endoscopically then initial treatment should consist of endoscopic coagulation. In some cases this fails and, in occasional patients, angiography demonstrates angiodysplasia which was not visible at endoscopy. In either of these situations, operative treatment may be required. It has become apparent that the presence of angiodysplasia does not necessarily mean that it is the source of bleeding or perhaps the only source of bleeding. Although angiodysplasia is an extremely rare incidental angiographic finding in patients without gastrointestinal bleeding, patients with angiodysplasia frequently have other lesions which are potential sources of haemorrhage. Meckel's diverticulum appears to be particularly common in this context, and jejunal arteriovenous malformations and small bowel tumours have also been found in association. Experience has shown that it is not possible to be certain about the source of haemorrhage when there are two possible sources of bleeding; if such patients come to laparotomy then both potential sources should be dealt with[2].

Bleeding diverticular disease has always been problematic. In the days before angiodysplasia was diagnosed commonly, the mystery remained that diverticular disease was always more extensive in the left colon although it was apparent clinically that bleeding occurred more commonly from the right side. In one series of 100 patients with 144 episodes of bleeding, it was noted that in 58 the bleeding was bright red in colour whereas in 42 it was black and tarry[3]. Left-sided resections were commonly followed by rebleeding, although the disease was more extensive on the left. This led to emphasis being placed on the importance of extensive colectomy when dealing with acute 'diverticular' bleeding, or to the need for a temporary transverse colostomy when deciding which half of the colon contained the source of bleeding before resection. It was noted, however, that bleeding was commoner in patients with extensive diverticular disease than in those where the disease was more localized. In today's context it is very important to question the diagnosis of bleeding diverticular disease. If at all practical, angiography should be employed to determine the site of bleeding. Undoubtedly many patients previously diagnosed as having bleeding diverticular disease were in fact suffering from angiodysplasia. If the patient is losing black tarry stool then angiodysplasia is even more likely, and if a 'blind' resection seems warranted then right hemicolectomy might be the logical choice. For severe red bleeding of unknown origin, subtotal resection of the colon may still occasionally be necessary.

0007–1323/89/010003–02$03.00 © 1989 Butterworth & Co (Publishers) Ltd

Where there is serious doubt and the general condition of the patient permits, an alternative option is the creation of a transverse colostomy followed by appropriate colectomy if bleeding recurs. The importance of a full, careful laparotomy, including detailed palpation of the small bowel, cannot be over-emphasized.

Ischaemic colitis rarely causes severe bleeding. When it does, the bleeding is characteristically plum-coloured and is associated with abdominal pain and tenderness. In 10 per cent of cases, ischaemic colitis follows surgery for aortic aneurysm. It can be diagnosed readily endoscopically or by barium enema, and angiography is not necessary.

Radiation-induced colitis commonly presents with bleeding. Radiation is most often given for intrapelvic disease of the female reproductive system or the bladder, and so the most commonly involved parts of the gut are the ileum and the rectosigmoid. In a series of 70 patients with 97 radiation-induced lesions of the gut, 36 involved the rectum and sigmoid[4]. Haemorrhage in such patients may be from a chronic proctocolitis, or may emanate from localized ulceration. Persistent bleeding, or recurrent acute bleeds, may lead to considerable disability. The Edinburgh experience illustrates the usefulness of proctectomy in this situation with excision of the involved rectal mucosa and a coloanal sleeve anastomosis[5]. Although this procedure is not undertaken lightly in such patients, it can bring to an end a cycle of haemorrhage and hospitalization for which no other treatment is effective. The splenic flexure must be brought down for such an anastomosis, as it is free from radiation damage.

Changing patterns in the treatment of rectal cancer

In the last decade, we have seen a technical revolution in the surgical treatment of rectal cancer. The introduction of stapling instruments has allowed the anal sphincter to be conserved in far more patients than previously. Contrary to the views of many Jeremiahs, this revolution has been achieved without an apparent decrease in survival rates or an increase in recurrence rates when compared with the results of abdominoperineal excision of the rectum[1–3]. It is true that selection is important, but there are now few patients who cannot be treated by sphincter-saving resection. The resulting quality of life is far superior to that associated with a permanent colostomy, although frequency of bowel action may still be an inconvenience for some patients with very low anastomoses[4]. However, even this relative imperfection may now be circumvented by the construction of a colonic pouch[5,6].

Despite this creditable performance by surgeons and instrument manufacturers in improving the lot of the patient with rectal cancer, the natural history of the disease has remained unaffected. Over the last 50 years longevity has not improved and, indeed, overall results are depressingly poor. In specialized centres, corrected 5-year survival rates in the last half-century have remained static at around 50 per cent—and this despite an almost 100 per cent increase in operability rates. The national data are likely to be far worse. In the early 1970s, the overall survival rates for rectal cancer in the midlands and in the south-west of the UK was 29 per cent and 23·5 per cent, respectively[7,8], and there is no evidence to suggest that these rates have improved. Another disturbing feature to emerge recently has been the surgeon-to-surgeon variability in local recurrence rates. Phillips and co-workers[9], when reporting the results of the St. Mary's large bowel cancer project, found that the incidence of local recurrence after rectal excision varied from less that 5 per cent to more than 20 per cent, depending on who performed the operation.

Where do we go from here? Have we as surgeons reached the end of the road as regards our ability to influence the natural history of the disease? Should we now accept the sentiments expressed by Sir John Ericksen in 1873: 'There must be a final limit to the development of manipulative surgery. The knife cannot always have fresh fields for conquest, and, although methods of practice may be modified and varied, and even improved to some extent, it must be within a certain limit. That this limit has nearly, if not quite, been reached will appear evident if we reflect on the great achievements of modern operative surgery.'[10]. Ericksen was mistaken in 1873, and, in my opinion, remains so in 1988 with respect to rectal cancer. However, if improvement is to be forthcoming, attitudes have to change and surgeons cannot be complacent. Technique must still play an important part in preventing recurrence; why else should there be so much surgeon-to-surgeon variation? It is true that some of these differences may be due to demographic differences, but they seem more likely to be due to variations in the extent of local tissue removal. We now know that the mesorectum and pararectal tissues frequently contain microscopic tumour deposits resulting from radial spread of the tumour[11]. Not only are such deposits not suspected by the surgeon at operation or by the pathologist on routine examination of the specimen but if left *in situ* they seem to be the main cause of local recurrence. Surprisingly also, abdominoperineal excision as performed by many surgeons is no more effective in eradicating this form of spread than sphincter-saving resection. It would seem prudent, therefore, that no matter which type of operation is performed, the whole of the mesorectum should be excised[12]. However, no matter how aggressive the surgeon is in dealing with this form of spread, it is unlikely that he will be able to remove it all. Clearly, some form of local adjuvant therapy is required. In our present state of knowledge, radiotherapy seems the most logical choice. It is of particular interest that, while many adjuvant radiotherapy trials have failed to show any overall improvement in recurrence rates, patients with fixed or partially fixed tumours seem to have benefited from even quite low doses of radiation[13]. As these patients are in the main those with macroscopic spread, one can only speculate on how effective the same treatment would be if it was directed at microscopic disease. Such a policy would necessitate an enormous increase in the workload of our pathologist colleagues, but would be justified if it proved to be beneficial. A controlled randomized trial is urgently required.

However, it must be accepted that even if such treatment reduces the incidence of local recurrence, it is unlikely to improve survival rates. To date, few trials of adjuvant

0007–1323/89/010005–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

radiotherapy (when given without chemotherapy) have been shown to prolong life, even if local recurrence rates have been reduced. Presumably, this reflects the fact that distant spread has occurred before or after local treatment has started. We know that approximately 30 per cent of patients with colorectal cancer have occult metastases at the time of surgery, and these cannot be detected by conventional scanning techniques[14]. Systemic adjuvant chemotherapy seems appropriate. It is of interest to note that in a recent large trial of adjuvant therapy in rectal cancer[15], the group of patients who received a combination of radiotherapy and systemic 5-fluorouracil and semustine was the only one to show a significant improvement in survival. This was not, however, achieved without significant morbidity. Such results suggest that this type of therapy is effective, but should be employed only for high-risk groups. This conclusion highlights the need for appropriate assessment and staging. We urgently require a means of detecting microscopic distant spread and perhaps the hepatic perfusion index will be the answer[16]. Even if it is not, a standardized method of assessment which takes into account the clinical and pathological characteristics of the disease needs to be established. Such a system might help to detect the high-risk groups, and it should also detect patients whose prognosis is so hopeless that they might be best treated by a local procedure as opposed to a more major resection. Such a system has recently been proposed[17] and it is to be hoped that these recommendations will be generally accepted.

The other great hope for improving the results of treatment is early detection of the tumour. We all await with interest the results of current controlled trials of faecal occult blood screening[18]. However, regardless of the outcome, surgeons will still be dealing with established and often advanced disease for a long time to come. If we are to make any impact on the eventual outcome, we must have a more uniform approach towards the disease, eliminate surgeon-to-surgeon variability in our results and be more prepared to enter our patients into adjuvant trials. Our considerable achievements in preserving continence must be matched by a concerted effort to improve survival and recurrence rates.

Choice of material for above-knee femoropopliteal bypass graft

J. A. Michaels

Department of Surgery, University College and Middlesex School of Medicine, London, UK
Correspondence to:
Mr J A. Michaels, Department of Surgery, The Rayne Institute,
5 University Street,
London WC1E 6JJ, UK

Autogenous saphenous vein is generally considered to be the best material for arterial bypass grafts below the inguinal ligament. Recent results have suggested that the advantage of vein over prosthesis is more pronounced in a distal situation, but it is not immediately apparent whether the difference is sufficient to justify a policy of using prosthesis for the initial above-knee graft to preserve the vein in case later surgery is required. An attempt has been made to answer this question. The literature has been reviewed to obtain estimates of the patency rates for grafts in different situations and a mathematical model has been set up using these figures to predict the outcome of different treatment policies. The model can be used to predict the result of alteration or inaccuracy in the data or to make use of the results of newly reported studies. The model predicts that the use of prosthesis for an initial graft will reduce the overall patency and substantially increase the requirement for reoperation, even if the present data give a substantial overestimate of the advantages of vein above the knee.

Keywords: Arterial occlusive disease, vascular graft patency, vascular prosthesis, saphenous vein, vascular surgery, models, theoretical

For the past three decades there has been a steady expansion of the available methods for the relief of symptoms due to vascular occlusion. Bypass grafting has become an established method, with autogenous vein being the usual preferred material where a vein of suitable size is available[1]. In other situations there is a variety of prosthetic materials to choose from. New materials have been introduced and shown to be satisfactory for replacement of large calibre vessels such as the aorto-iliac arteries, but it is generally accepted that autogenous vein is better than a prosthesis in the case of arterial disease distal to the inguinal ligament[2]. Recently, however, there have been many series of patients in whom some of the newer materials have been used in this situation with reasonable results. The results, as would be expected, seem to be at their best in situations of high flow and correspondingly low risk. In particular, some studies have failed to show a significant advantage for vein when used for above-knee femoropopliteal bypass[3,4]. This has led several authors to suggest that synthetic materials should be used as first choice in these situations and the vein preserved for later coronary or distal grafting, where the advantages of vein are well established[5–7].

To establish whether such a policy can be justified on the present evidence certain questions need to be answered. Does the existing evidence give an indication of differences in patency rates between vein and prosthesis when used above the knee? If there is such a difference, are there arguments in favour of preservation of the vein? Finally, are the potential benefits sufficient to outweigh any possible disadvantages?

Published evidence

Many published studies describe the results of using various types of peripheral vascular grafts in different situations. Unfortunately there are difficulties in attempting to compare the results of different series[8]. There are many materials and surgical techniques and there are a multitude of known and putative risk factors, the incidence of which varies from one series to the next. There is a paucity of controlled randomized trials, most studies using historical or non-randomized concurrent controls, and not all trials use the same definitions in describing symptoms and results[9]. Bearing these reservations in mind, the present evidence has been reviewed (*Tables 1–4*). The studies quoted in the tables are limited to those published over the past 10 years as development of surgical techniques, changes in indications for surgery and new graft materials make comparisons with earlier results of doubtful value. The studies quoted are also limited to those in which the results could be extracted separately for groups of patients almost completely composed of those having either prosthetic or vein graft above or below the knee. Papers were located by a computerized literature search followed by a manual search of the major

surgical journals. This identified over 120 reported series of femoropopliteal grafts of which approximately one-third contained sufficient detail for them to be included.

The results reported here confirm that there is a considerable difference in long-term patency between vein and prosthetic material, more pronounced in the below-knee site. Most of these trials confirm the tendency for there to be a high initial failure rate, with a slower, almost constant attrition rate over subsequent years (*Figure 1*). For this reason the results have been presented as rates of occlusion in the first year and an average for subsequent years. This allows for the pooling of more data from studies in which the results are presented after differing time periods.

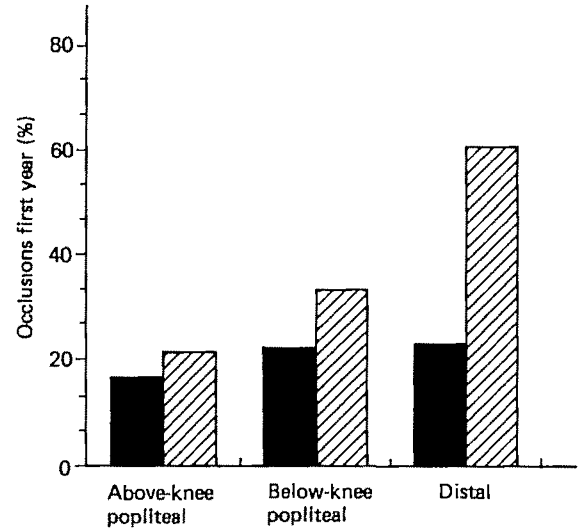

Figure 2 *Occlusion rate in first year* versus *anastomotic site for vein and prosthetic grafts.* ■, *Vein grafts*; ■, *prosthetic grafts*

Several factors which may influence the results of surgery vary between groups. The site of the distal anastomosis in below-knee grafts is a possible risk factor (*Figure 2*) with distal grafts having a worse prognosis especially when using prostheses. Opinions vary about the relative merits of different prosthetic materials[41,42] but it seems to make little difference overall (*Figure 3*) except that polytetrafluoroethylene (PTFE) has better reported results than Dacron below the knee but not as good above the knee. A possible explanation for this lies in the differences in mechanical properties which may make Dacron more suitable in situations where it is not necessary to cross a

joint[43]. Individual studies have shown that operations for salvage fare worse than those for claudication[16] but there is no good correlation in the overall trend.

Evidence in most situations suggests that vein is better than prosthetic material for long-term patency This is seen to be most marked in situations where there is known to be a high risk of failure. In the coronary circulation the vein is considered far preferable to any prosthesis[44]. In peripheral disease the factors which indicate high risk of re-occlusion—such as poor run off[45,46], critical ischaemia[45–47], distal grafting[46,48,49] and continued smoking[48,50]—all seem to accentuate the disadvantages of using a prosthetic graft. In none of the studies reviewed does any prosthesis have superior results to vein in any situation. In the case of above-knee grafts there seems to be little difference in the first-year results but a much higher attrition rate for the prosthetic grafts in subsequent years. This is particularly important as the follow-up is sometimes incomplete and is made more difficult by the death rate in patients with femoropopliteal atherosclerosis[16]. In those studies in which it was specified, the average yearly mortality rate was approximately 10 per cent, giving an overall 5-year survival of about 59 per cent.

The problem of inadequate follow-up is well demonstrated in several trials in which the authors have come to the conclusion that there is no significant advantage in the use of vein[6,14,17]. Of these trials the largest 5-year follow-up in the vein graft group is based on 24 patients. In this situation, type II statistical errors become a problem with a <50 per cent chance of showing a statistical difference between the groups even if the true difference in 5-year patency is >25 per cent Added to this is the further problem that none of these trials is randomized, therefore doubts must exist about the comparability of the treatment groups

One randomized controlled trial of a reasonable size has been reported by Bergan *et al.*[51] and Veith *et al.*[18]. In this trial 845 infra-inguinal bypasses were performed with randomization to autologous saphenous vein or PTFE. The results obtained broadly follow those suggested by the accumulated data reported above For most groups a statistically significant advantage for autologous vein is shown. Again, however, the advantage shown for vein in the above-knee situation (61 per cent *versus* 38 per cent patency at 4 years) is not statistically significant due to the very small number of patients who could be followed for this length of time, even in this very large and prolonged multicentre trial. There are other problems in the interpretation of this trial, particularly regarding the randomization procedure Patients were randomized before investigating whether there was an adequate vein for bypass, and this was only established at the time of surgery in those patients who were allocated vein grafts. This led to a large number of patients being excluded from the vein graft group and forming an 'obligatory PTFE' group. When the results were analysed this group fared significantly worse than the randomized PTFE group. This suggests that either there was some unintentional selection taking place or that vein quality is an indicator of the likelihood of prosthetic graft failure.

In order to use accurate estimates for further modelling it would be desirable to combine the results of all the reported studies to obtain patency rates and confidence limits for the combined data. Statistical methods for doing this, termed 'meta-analyses', have been described and discussed in the medical literature[52,53] Several problems are encountered in trying to apply these techniques to the present study. Many of the reviewed papers present inadequate data for the results of different materials in different situations to be individually assessed, most of the reported studies are uncontrolled, and where there are controls these are usually non-randomized Using the few controlled trials of above-knee grafts that have sufficient data[4,10,11,13–15,18] the homogeneity was assessed graphically as described by L'Abbé *et al.*[52] (*Figure 4*). The results appear consistent and the two series with <25 per cent risk reduction have a high proportion of claudicants[4], or are a subgroup composed only of claudicants[11].

Taking these few studies and analysing the combined data for prosthesis against vein graft above the knee using the Mantel–Haenszel statistic[54] gave a result significant at the 0·05 level after the first year and figures significant at the 0·01 level after 2 and 3 years. It must be noted that these results are based on only a small group of studies from which some of the data had to be calculated and sometimes extracted from graphical presentations as the raw data were rarely published.

Overall, there seems to be close agreement between the one sizeable randomized trial and the figures for both the unrandomized controlled studies and the collected uncontrolled data. However, these points do not exclude the possibility of a selection bias common to all the trials, or a reporting bias.

Despite reservations about the quality of the data the figures presented are the best estimate that is currently available and, until much larger randomized trials are reported, this is the information on which clinical decisions must be based. It can be seen that the vein graft has the best reported patency in all situations The question remains about whether there is any potential advantage in using prosthetic material rather than vein that would justify its preferential usage.

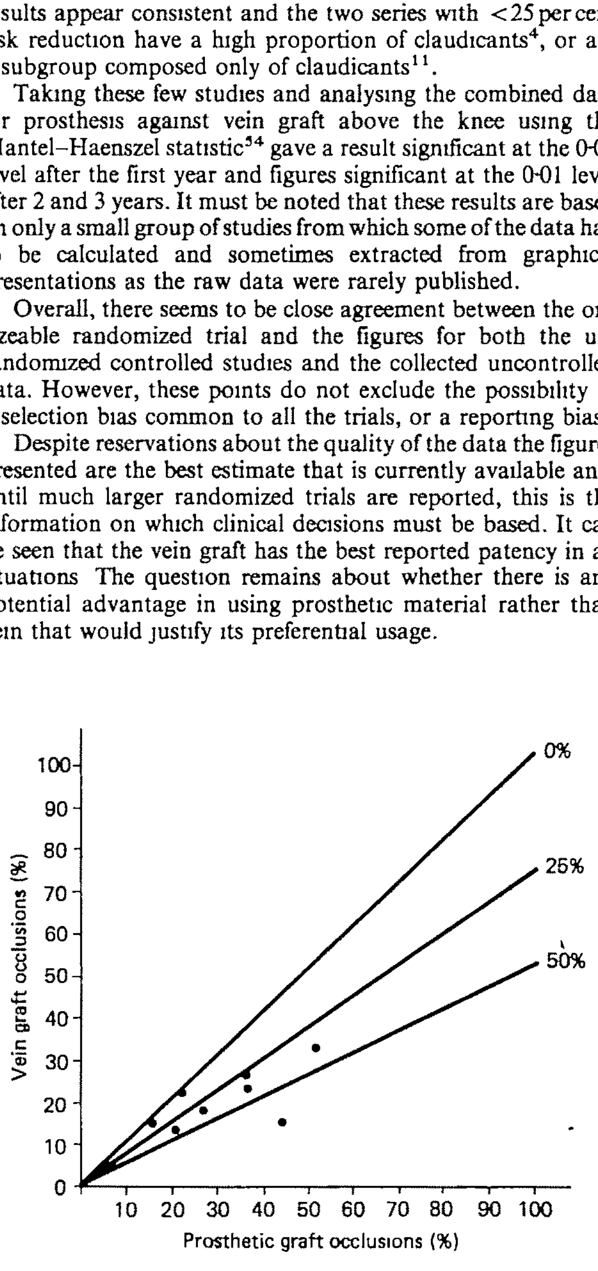

Figure 4 *Homogeneity of controlled trials of femoropopliteal grafts above the knee at 2 years Lines represent 0, 25 per cent and 50 per cent reduction in hazard rate for vein compared with prosthetic grafts*

Two main arguments have been put forward. Firstly, that the operation is faster with fewer complications and, secondly, that it is desirable to preserve the vein in case it is required later for coronary or distal bypass where the advantages of its use are more marked.

Although it is generally agreed that the operation using a prosthesis is quicker, the case for corresponding reduction in mortality and morbidity has not been shown by any of the trials referred to above, and does not necessarily follow because of the potential for increased morbidity due to the introduction of a prosthesis and the associated increase in risk of infection[20,55].

The question of vein preservation for coronary surgery does not stand up to close scrutiny. Firstly, it could only, logically, be applied to operations on the second leg, and only a minority of patients has surgery to both legs[56] Secondly, although it is well established that ischaemic heart disease is a major cause of mortality after peripheral vascular surgery, the number of patients who come to cardiac surgery is small[57], perhaps partly because restraints on resources in this country make the operation uncommon in the age group that undergoes peripheral vascular surgery. Also, the availability of satisfactory alternatives such as the internal mammary artery and the short saphenous and arm veins, means that the lack of a saphenous vein due to prior use for limb revascularization is unlikely to be encountered as a major problem.

The remaining question is whether the advantages, which have been shown for the use of the vein in the below-knee situation (*Tables 3–4*), are sufficient to justify its preservation at the time of original surgery in case later salvage surgery is required.

Mathematical modelling

In order to attempt to answer this question a mathematical model has been set up using a computer spreadsheet to study the results of various treatment policies on the overall patency and number of operations required. This is carried out by considering a time interval and determining from the available data what proportion of patients are expected to be subject to various events, such as graft failure, salvage surgery or death The number of patients remaining at risk at the end of the period can then be calculated and the process repeated for the next period. In this way the overall results in terms of the proportion of patients requiring revision of their grafts, and those with patent and occluded grafts, can be estimated from the published data. By assuming different treatment policies and entering different basic data, new sets of results can be repeatedly generated to model a different set of circumstances.

For this to be done certain assumptions and simplifications are made:

1. The occlusion rate for each type of graft is presented as an occlusion rate for the first year and an average rate per year for subsequent years. As discussed above this produces a close approximation to the published data and allows the pooling of a larger number of studies
2. Mortality is taken as two components, a figure for operative mortality and an average yearly figure for overall mortality. Operative mortality for the initial above-knee operation is about 5 per cent and has not been shown to depend on graft material. For subsequent salvage procedures the operative mortality has been taken as 5 per cent which is an average of several reported figures for this type of operation[30,58–62] For the average yearly mortality a rate of 10 per cent has been obtained from a survey of several papers[13,56,62–64], which, as stated above, is equivalent to a cumulative survival of about 59 per cent at 5 years.
3. A further figure which is required for the model is the proportion of graft occlusions which lead to the need for further surgery. It is known that many grafts occlude without symptoms or with symptoms that are not sufficient to warrant further intervention[8] For the model it has been assumed that all patients with occluded above-knee grafts whose condition deteriorates would require further surgery, that this would always be a below-knee procedure and that no patient would have amputation without an attempt at salvage surgery. Since those patients without an adequate vein do not have a choice of initial treatment, it is assumed that those in whom the vein was used at the initial operation would have to have a prosthetic graft and that the others would all have a vein available for the salvage procedure. The evidence from several studies is that the proportion of occlusions which require further surgery on these criteria is about 50 per cent[65] although there are some differences between those in whom the initial operation was for claudication and those in whom it was for critical ischaemia[66,67].
4. The model only takes account of second operations for limb salvage. The possibility of third and subsequent attempts at limb salvage is ignored. There is little evidence that these play a significant part in the overall results, and in any case the vein would no longer be available and so the subsequent course is independent of initial treatment.
5. The model assumes that mortality and graft occlusion are independent apart from the operative deaths This is probably largely true as the major causes of mortality in this group of patients are ischaemic heart disease and cerebrovascular disease, and peripheral vascular disease is only implicated as a cause of death in a small number of cases[56].

Having constructed the model with these constraints the appropriate figures have been extracted from the reviewed literature as described above. The results are shown in graphical form in *Figure 5*. They show a clear overall advantage in using the vein in the initial graft, while the alternative increases the number of additional operations and also causes a lower 5-year patency when considering both first and second grafts. There is also a slight increase in mortality owing to the operative mortality associated with the larger number of salvage procedures.

It is clear that these figures are based mainly on non-randomized trials and so the original data are open to question. However, if one looks at the overall results from both collected published data and the large randomized trial referred to above then it is suggested that the advantage of using vein in the above-knee situation is an improvement of approximately 40–60 per cent in the expected 5-year patency rate. Even if this is an over-estimate and the real difference is only half this then the results of the model still hold.

It is worth looking at some of the implications of this. Using the method described by Remington and Schork*[68] for estimation of sample size and assuming there is actually a 20 per cent difference in 5-year patency, the number of grafts required at 5 years in order to have a 95 per cent chance of showing significance ($P < 0.05$) is about 160 in each of 2 randomized groups Because of the high mortality and loss from trials, and the fairly small proportion of patients who would be suitable for initial randomization, it would require an extremely large group of patients to have a good change of this level of follow up. It is of note that none of the trials reported to date has managed to accumulate 5-year follow up on even half this number of patients

There is a difference in the outlook for certain subgroups, for example those with good or poor run off, smokers and non-smokers, diabetics and non-diabetics, or those with claudication or critical ischaemia It would therefore be desirable to study these groups separately with a resulting multiplication in the number of subjects required

---

* *There are methods available for the estimation of sample size in life table analyses but these require assumptions about the nature of the hazard function and, because of the high level of censoring of data expected in this kind of trial, these estimates differ little from those provided by the method used*

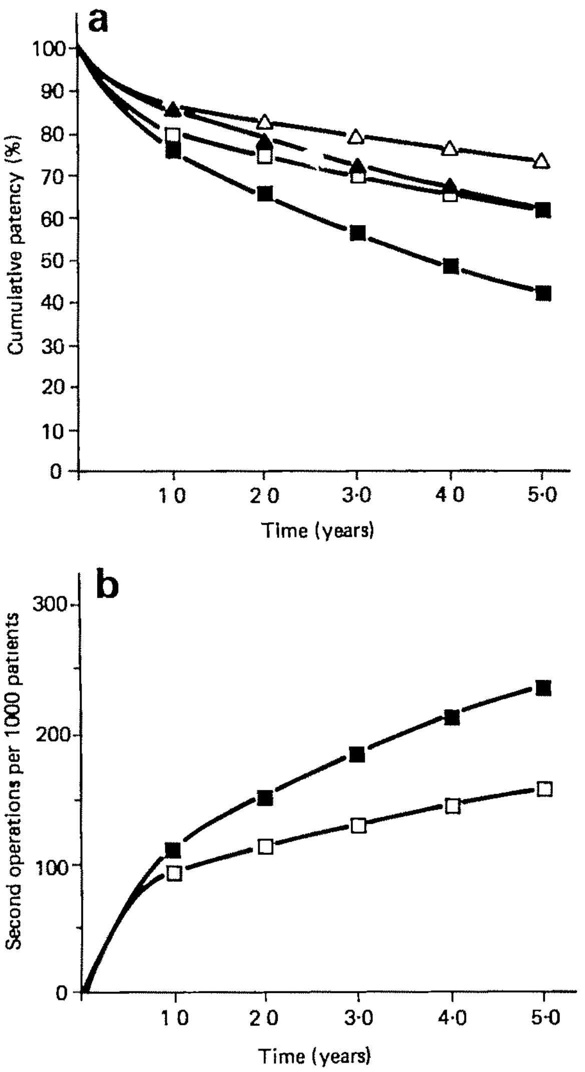

Figure 5 *Results of model comparing vein with prosthesis as an initial above-knee graft* **a** *Patency of initial graft and patency including reoperations* □, *Vein first primary patency;* △, *vein first total patency;* ■, *prosthesis first primary patency,* ▲, *prosthesis first, total patency.* **b** *Number requiring second operations* □, *vein graft first,* ■, *prosthetic graft first*

As mentioned before there seems to be a trend towards more marked differences in patency between vein and prosthesis when the chances of failure are higher. However, this may be partly due to a statistical problem in that it is far more difficult to show a difference in the incidence of an event if there is a low event rate For example, assuming that the 5-year patency for vein grafts was 60 per cent and a prosthesis was 50 per cent more likely to occlude in a given set of circumstances, it would require about 160 patients in each group to have a 95 per cent chance of showing the difference. However, to show the same percentage increase in occlusions in a lower risk group, with an 80 per cent 5-year patency for the vein graft, would require more than twice as many patients This point is demonstrated graphically by Friedman *et al.*[69].

Discussion

All the evidence reviewed suggests an advantage in using vein for above-knee bypass grafting. If there is really no difference in the results then it would be surprising that not one of these trials suggests, purely by chance, that any prosthetic graft is better than vein As has been seen above there is considerable difficulty in designing a trial which would have sufficient 'power' to have a good chance of showing a difference of the order of 10–20 per cent in 5-year patency in a subgroup of patients with infra-inguinal disease. However, the mathematical modelling confirms that even a small difference in 5-year patency could not be compensated for by the advantages of saving the vein for later salvage procedures and no other reasonable argument has been substantiated for the preferential use of a prosthesis.

A different approach to this problem is to look at a situation in which it is more likely that a difference will exist. For example, it is established that the 'quality' of the vein as judged by the operating surgeon is an indicator of its likely long-term patency[16]. Despite this, different series show widely differing rates of vein usage[24,33,70–73] so it would seem reasonable to undertake a prospective trial in which the poorer quality veins are compared with a prosthesis.

Another area which requires further study is that of improving the results for distal bypass when the vein is not available. Recent papers reporting promising results when using jump grafts[74,75], composite grafts[76–78] and alternative veins[79–81] may offer some hope in this respect

Perhaps one of the most important conclusions that arises from a review of the literature is a recognition of the statistical problems of drawing conclusions from insufficient data. This has been demonstrated by Frieman *et al*[82], who found in a review of 71 clinical trials that most had a high chance of missing a difference in result that would be considered to be clinically relevant. This is just as common in other areas of research[83] and in this case it is unfortunate that so many conclusions have been drawn based on data that are not sufficient to exclude a sizeable difference in 5-year patency.

It may be that with developments in graft materials, further controlled trials will identify a group of patients in which an initial prosthetic graft has an advantage. However, on the present evidence, the overall conclusion must be support for the traditional view that autogenous saphenous vein remains the graft material of first choice for all infra-inguinal bypass surgery.

Complications of intravenous nutrition are uncommon but may prove problematic in patients requiring long-term nutritional support. This article reviews the complications associated with intravenous catheters with particular emphasis on problems associated with insertion, catheter-related sepsis, venous thrombosis, catheter occlusion, endocarditis and intracardiac thrombus formation.

Keywords: Intravenous feeding, sepsis, complications

Parenteral nutrition is widely used to support the treatment of patients with severe sepsis, trauma and gastrointestinal malignancy, and home parenteral nutrition has an established place in the treatment of intestinal failure. Of the many advances which have made long-term parenteral nutrition feasible, the development of the Silastic® (Dow Corning, Reading, UK) catheter[1] has been arguably the most important, enabling safe, reliable central venous access.

Complications of parenteral nutrition are uncommon but may pose considerable problems of management in those requiring long-term nutritional support. Outside specialist centres, catheter sepsis remains the most common complication, resulting in a considerable morbidity and frequently leading to the premature termination of treatment. Yet compared with many other aspects of parenteral nutrition little has been written about the potential for, and the morbidity of, catheter-related complications.

Improvements in the design and care of catheters have considerably reduced the incidence of infection, occlusion and mechanical failure but cases of symptomatic central venous thrombosis are being reported in ever-increasing numbers[2–5]. The most extreme form of this complication, occlusion of the vena cava, poses great difficulties in re-establishing central venous access and may be further complicated by a number of potentially fatal complications such as pulmonary embolism. Although it is unlikely that the actual incidence of central venous thrombosis is rising, greater awareness and the increasingly widespread use of parenteral nutrition are bound to increase its prevalence. A further serious problem is that of intracardiac thrombus formation, a complication which has only recently been recognized[6–10].

The object of this paper is to review the incidence, aetiology and management of catheter-related complications with emphasis on prevention.

Complications of insertion

Complications directly attributable to catheter insertion occur in 3–12 per cent of cases[2,11–13]. Virtually any structure in the vicinity of the vein being catheterized can be injured but the most frequent injuries, reflecting the popularity of the percutaneous infraclavicular approach to the subclavian vein, are to the pleura or subclavian artery. A significant pneumothorax requires a chest drain but a mediastinal haematoma is often self-limiting and does not usually require specific treatment.

Catheter embolism is rare now that the dangers of inserting plastic catheters through metal needles are widely recognized. Should it occur, the embolus usually can be recovered by a radiologist experienced in interventional methods[14]. Air embolism may occur during insertion from faulty technique, but it is more commonly due to the accidental disconnection of the drip tubing[15], a complication that can be avoided by using Luer-lock connections.

Certain complications presenting many hours or even days after a seemingly straightforward procedure may also be attributable to insertion. For instance, rupture of the innominate vein[16] and hydrothorax have been reported days after satisfactory use of an easily inserted catheter. The exact mechanism of such a presentation is unclear but rupture of the vein has been attributed to the repeated movement of an incorrectly positioned catheter tip against the vein wall, especially when using stiff catheters[17]. However, 'osmotic' injury from hyperosmolar solutions may also be a factor[18]. Rare complications include perforation of the chambers of the heart[19–22], pulmonary artery[23] and inferior vena cava[24] with or without cardiac tamponade. One of the most bizzare complications reported is paraplegia due to infusion into the spinal canal[25].

Catheterization by cut-down has been advocated by some on the basis that it is safer than percutaneous insertion. Exposure and catheterization of the superficial veins (the basilic at the elbow, the cephalic below the clavicle, the external jugular and the saphenous) is relatively simple and safe. However, the advantages of catheterization under direct vision may be outweighed by the potential complications of exposing major veins such as the axillary or the internal jugular in the hands of those without special expertise. In fact, in experienced hands both percutaneous catheterization and cut-down have a low and comparable morbidity[26,27]. In most cases it should be possible to insert a catheter either by percutaneous puncture or cut-down onto a superficial vein. Formal exposure of major veins, which may require general anaesthesia, should now only be necessary for inserting especially large calibre catheters and when percutaneous puncture is considered hazardous (as in those with a bleeding tendency) or has failed. Using vessel dilators and peel-apart sheaths even large calibre, cuffed catheters can now be inserted percutaneously by the Seldinger technique.

Complications can be kept to a minimum by careful attention to technique and concentrating experience in the hands of a few interested individuals. The best time to correct errors is during the procedure and the operator should satisfy himself that the catheter is correctly sited by ensuring that blood can be freely aspirated through it and by checking its position by X-ray. An image intensifier considerably simplifies positioning by allowing one to see the effects of catheter manipulation on the position of its tip.

Catheter-related sepsis

The incidence of catheter-related sepsis varies between 2·8 and 14 per cent[12,28–33], but virtually sepsis-free parenteral nutrition possible as shown by Sanderson and Dietel[34] who reported only one episode of infection in 100 patients treated for a total duration of 6·2 patient-years. The reported incidences also require careful interpretation. Incidence alone is not particularly meaningful as, for the same reported incidence of catheter-related sepsis from two centres, the results of the centre reporting

0007-1323/89/010015-07$3 00 © 1989 Butterworth & Co (Publishers) Ltd

the fewer episodes per patient-year of catheter use are obviously better

What constitutes catheter-related sepsis? A positive culture from blood drawn through a catheter may equally be due to bacteraemia arising from a pelvic abscess, for instance, as to organisms liberated from a colonized catheter. Furthermore, a scant growth of skin commensals from the tip of a catheter removed after uneventful use is much more likely to be due to contamination during withdrawal[35] than to catheter sepsis. Diagnosis of catheter-related sepsis requires that the same organism is grown from the catheter tip as is recovered from the blood[28] and that the clinical features of infection resolve on removal of the catheter. By these criteria, however, catheter-related sepsis can be proved only by removing the catheter, and some 'clean' catheters will inevitably be removed. Such wastage can now be avoided by using a recently described technique[36] which entails culturing samples of blood drawn simultaneously through the catheter and a peripheral vein. If the colony count in the catheter blood is five or more times that in the peripheral blood, catheter-related sepsis is highly likely. The high predictive value of this technique has been confirmed by others[37]. It should therefore no longer be necessary to remove catheters merely on suspicion of sepsis except in special circumstances

Catheters become infected either during insertion or subsequently through poor care. Catheters should be inserted with the same care as other prosthetic devices such as cardiac valves and artificial hips. A full aseptic technique is mandatory and reports of 'acceptable' infection rates in catheters inserted outside the operating theatre[11], in the author's opinion, set a dangerous precedent. The only acceptable infection rate following catheter insertion is zero. Not surprisingly the incidence of infection correlates directly with the number of attempts made at insertion[29] and inversely with the experience of the operator[33]. Prophylactic antibiotics do not appear to influence infection rates[38].

How then does an aseptically inserted catheter become infected? Because of the high standards now pertaining to their manufacture and storage, it is rare for feeding solutions to be the source of infection. The consensus of opinion is that infection arises from the catheter hub, which was found to be colonized by organisms in 70 per cent of patients with catheter-related sepsis in one study[39]. Regular dressing of the catheter exit site dramatically reduces the number of positive cultures from swabs taken from the exit site and the external portion of the catheter[40] and the value of strict catheter care protocols in reducing sepsis has now been confirmed by many centres worldwide. It has clearly been shown that catheter-related sepsis rates are lowest when catheter care is entrusted to designated nutrition nurses[41–43]

Until recently it was widely believed that placing the catheter in a subcutaneous tunnel reduced the risk of infection by preventing the migration of organisms from its hub to the intravenous portion. Controlled studies have shown that tunnelling does not in itself affect the infection rate[41,44,45] but it does enable the catheter to be brought out where it is easy to handle and dress, and this may indirectly reduce the potential for infection

The available data on infection rates in multipurpose catheters require careful appraisal. For instance Apelgren[46] found that 14·3 per cent of triple lumen catheters removed from patients in the intensive care unit were infected whereas Kaufman and colleagues[47] reported only a 3·8 per cent infection rate in multilumen catheters used in a similar setting. In both studies the catheters had been used for sampling, monitoring and administering drugs as well as for parenteral nutrition. The data reported by Pemberton and colleagues[48] offer an explanation for this discrepancy. They found a 19 per cent incidence of sepsis in triple lumen catheters compared with 3 per cent in single lumen catheters used exclusively for parenteral nutrition, yet the catheter exit site was infected in 5 and 3 per cent of cases respectively in the two groups. This suggests that although the catheter exit site was cared for equally well in patients with both kinds of catheter, infection was probably introduced into multilumen catheters during sampling, monitoring and the administration of drugs. It is well known that such procedures are not usually performed with the same regard to asepsis as that which pertains when parenteral nutrition solutions are set up. That infection may be introduced in this way has been shown in one study which found evidence of bacterial contamination of intravenous fluids in 50 per cent of the bags to which drugs had been added by the nursing staff on the ward[49]. Provided that a strict catheter care protocol is maintained, multilumen[43,50] or multiple[51] catheters are no more liable to become infected than single lumen catheters that are being used exclusively for parenteral nutrition

A logical way of protecting the patient from the dangers of contaminated solutions is to use bacterial filters. However, the filters which are most effective in trapping micro-organisms, i.e those with a pore size <0·2 μm, unfortunately also trap lipid particles. Although a larger pore size solves this problem, it does so at the expense of a reduced efficiency of microbial filtration and a clinical study using a 0·4 μm pore size for parenteral nutrition failed to show any significant reduction in infection rates[52]. This, combined with cost, has limited the application of filters in parenteral nutrition.

In a bench model, catheters can be consistently colonized by perfusion with solutions containing bacteria[53], but there are no clinical studies which have investigated the circumstances in which catheters can become infected by seeding from endogenous sources of sepsis. A higher catheter infection rate in the presence of a urinay tract infection has been reported[54] but in the author's experience catheter-related sepsis is uncommon in patients with intra-abdominal sepsis unless this is complicated by recurrent septicaemias. When catheters do become infected, the most common organisms are staphylococci (most often coagulase negative) and fungi[32].

Both antibiotic and antiseptic bonding of catheters are currently being evaluated. In an animal study, antibiotic bonding reduced the likelihood of bacterial colonization of the catheter over a considerable period[55]. Clinical trials of such devices are in progress but whatever the outcome their use should be restricted to special cases for fear of encouraging bacterial resistance and, worse still, colonization by fungi

In one study[56], catheter-related sepsis was reduced when heparin was added to the infusion solution, the explanation advanced being that heparin prevented the formation of a fibrin sleeve capable of supporting organisms. More recent work has failed to confirm the value of heparin[57], which is not surprising considering that electron microscopy of infected catheters has shown bacterial colonies attached to the surface without the aid of a fibrin sleeve[58].

How should catheter-related sepsis be managed? Catheter salvage rates of over 70 per cent have been reported simply by using a long course of appropriate antibiotics[59,60]. The author has not had any success with catheter salvage using antibiotics alone but has obtained encouraging results using a fibrinolytic agent (to clear the catheter of any surrounding infected clot) combined with an appropriate antibiotic. This approach, originally introduced to the Nutrition Unit at Hope Hospital by Professor Jeejeebhoy of Toronto, has been used to salvage four out of seven infected catheters. The following protocol was used. On suspicion of catheter infection, blood for culture is drawn through the catheter which is then 'locked' with a solution containing 5000 units urokinase and 1 g flucloxacillin. Intravenous feeding is discontinued and flucloxacillin started in maximal doses parenterally. If signs of infection do not resolve within 48 h the catheter is removed unless blood cultures reveal an organism resistant to flucloxacillin, in which case the procedure is repeated using an appropriate antibiotic. Parenteral nutrition is recommenced 48 h after clinical resolution of the infection.

Worthley recommends treating catheter-related sepsis by flushing the catheter with 2M hydrochloric acid[61]. Although I have no personal experience of this technique it makes sense to treat infection with an antiseptic rather than an antibiotic In this context, Taurolin® (Geistlich Sons Ltd., UK) is a promising intravenous antiseptic which I have used successfully for the treatment of catheter-related sepsis. Taurolin is a derivative of taurineamide and formaldehyde (bis(1,1 dioxoperhydro,1,2,4 methylene thiadiazinyl-4) methane), with a broad spectrum of activity against bacteria and fungi. It is non-toxic in man, being metabolized with a short half-life to taurine, carbon dioxide and water[62] There are few objective data on any of the methods described above for salvaging infected catheters and this area requires clarification by further research.

Infected catheters that cannot be salvaged will have to be removed. When vascular access is limited it is obviously an advantage if the catheter can be replaced over a guidewire. Infection of the new catheter has been shown to be no more likely if it is substituted for the infected catheter over a guidewire or placed at another site[28]. Replacement over a guidewire is economical with regard to access sites and intravenous feeding is not interrupted[29]. The technique is not, however, always feasible. Unless the replacement catheter is made of stiff material, vessel dilators and peel-apart sheaths will be required to create and maintain a track through which catheters made from very flexible material such as Silastic can be pushed. Furthermore it is now recognized that some degree of venous thrombosis is present in association with approximately 50 per cent of catheters (see below). Replacement over a guidewire may cause greater disturbance to the clot when compared with simple removal[63] and for these reasons it has been the policy at Hope Hospital to insert a new catheter at a different site

Venous thrombosis

Routine venography has shown that venous thrombosis complicates 45–59 per cent of catheters[2,64,65] and yet only 2·5–4·8 per cent of patients[4,12,66] have symptoms and clinical signs Possible aetiological factors include thrombogenicity of the catheter material, mechanical or 'osmotic' damage to the vein wall, and cumulative intimal damage from repeated catheterization of the same vein.

Thrombus can be seen surrounding the catheter within days of insertion[66,67]. Data from the United Kingdom Home Parenteral Nutrition Register did not reveal any correlation between the incidence of thrombosis and the duration of treatment[4], indicating that osmotic injury is not an important aetiological factor. There is also experimental evidence showing that the incidence of venous thrombosis is not related to the osmolality of the infusion solution[63].

The presence of catalysts and stabilizers used during the manufacture of catheters may encourage thrombosis[68] The material from which the catheter is made may also play a significant role. Bozzetti *et al* [63] found venographic evidence of thrombosis in 46·1 per cent of polyvinyl chloride catheters compared with 11·5 per cent of Silastic catheters. Polyurethane may be even less thrombogenic than silicone elastomer owing to the smoother surface topography of catheters made from it[69].

In one study, Hickman catheters were associated with a higher incidence of clinical major vein thrombosis compared with the smaller bore Broviac and uncuffed catheters[4]. However many patients with Hickman catheters had previously required replacement of their catheter on more than one occasion because of either recurrent occlusion or sepsis. In such cases the higher incidence of thrombosis was therefore likely to be a consequence of repeated catheterization

To minimize venous thrombosis it has been recommended that those patients requiring long-term parenteral nutrition should be anticoagulated[2,65] However, Ladefoged's group[2], which adopted and recommends such a policy, has reported death from subdural haematoma in one of their patients. To avoid such complications the value of partial anticoagulation has been studied. Heparin in a dose of 1 unit/ml of infusion fluid (amounting to 3000 units daily in the average case) did not decrease the incidence of venous thrombosis[63], but prospective controlled trials have shown a marked reduction in the incidence of venographically proven thrombosis in those given heparin at a concentration of 3 units/ml[70] and 20 000units every 24 h[71] On this evidence the amount of heparin given with the feeding solution at Hope Hospital was changed from 1 unit/ml to 3 units/ml from the beginning of 1987 because the incidence of clinical central venous thrombosis had been unacceptably high at about 4 per cent. It is too early to assess the effect of this measure.

Before employing anticoagulant regimens to minimize venous thrombosis it is well to keep the scale of the problem in perspective. First, we know that the incidence of thrombosis bears little relationship to the duration of catheter use and, second, over 95 per cent of patients do not manifest any clinical problems related to thrombosis even though routine venography shows evidence of thrombosis in up to 50 per cent of cases. For the present, a pragmatic approach would be to use heparin in a dose of 3 units/ml of nutrient solution until it is possible to identify more clearly those patients who are at greatest risk of developing thrombosis, and who might merit full anticoagulation. Jacobson and Brismar have found that patients with a haemoglobin concentration >12·7 g/dl before parenteral nutrition have a high risk of developing thrombosis[72]. If these findings are confirmed, they could provide a rational basis for selecting patients for full anticoagulation.

Management of clinically significant major vein thrombosis is a difficult problem. The usual presentation is with limb swelling or with the syndrome of superior vena caval obstruction. The recommended management of unilateral arm swelling is removal of the catheter, anticoagulation and elevation of the limb[73]. In the author's view it is not necessary to remove the catheter unless it is infected, the position of its tip is unsatisfactory, or its lumen is occluded The catheter can be left in place but is not used until the swelling has subsided while extension of thrombosis is prevented by anticoagulation for a period of 6 weeks.

The real challenge is posed by superior vena caval thrombosis, which carries a mortality rate of up to 50 per cent. In this condition the catheter is often removed when it ceases to function because its tip has become embedded in clot. However, if the lumen is patent the catheter should be left in place, removal does not relieve symptoms or hasten resolution of the thrombus and it removes vital central venous access. Additionally the catheter may be useful for the local administration of fibrinolytic therapy which has been used with dramatic success to clear the thrombus by some groups[74,75].

Central venous access can be gained in several ways when the original catheter is occluded and the superior vena cava, along with its major tributaries is thrombosed. The simplest method is to use the saphenous or femoral veins for access into the right atrium. Indeed in children, Mulvihill and Fonkalsrud[76] found that whereas the incidence of major vein thrombosis was 20 per cent in right atrial catheters inserted via the superior vena cava, the incidence of thrombosis of the femoral vein or the inferior vena cava from catheters inserted via the saphenous vein was only 4·9 per cent The same group has also shown that unlike superior vena caval thrombosis, it is rare to develop life-threatening or fatal complications as a result of inferior vena caval thrombosis[77].

Many ingenious ways of establishing vascular access have been described, and the choice depends on a careful clinical assessment, the results of venography and the available expertise. Venography may reveal large collateral veins leading into a patent portion of the superior vena cava and even the intercostal veins may become sufficiently large to enable a catheter to be passed into the right atrium via the azygos system[78]

If no satisfactory collateral veins can be found, it may be possible to introduce a guidewire from the femoral vein into the right atrium and, under X-ray control, to manipulate it through the clot in the superior vena cava into an accessible tributary such as the internal jugular vein. The guidewire is then recovered by exposing the vessel and a catheter is pulled forcibly into the right atrium using a Dormia basket passed over the guidewire This technique has been successfully used in three patients without morbidity or mortality[3]. Nevertheless it has the potential for serious complications, and is probably best reserved for patients in whom safer and simpler alternatives have failed, and only if special radiological expertise and facilities for dealing with the possible complications are available. In centres without the necessary special expertise, direct catheterization of the right atrium[79], although a major operation, is probably safer than the percutaneous method described above.

An option that is frequently not considered is to provide parenteral nutrition through an arteriovenous fistula. This has been used successfully by a number of centres[80,81] and, despite its drawbacks, may provide satisfactory access while allowing the central venous system to recover before further attempts are made at re-establishing central venous access.

The natural history of central venous thrombosis is unknown since there are no satisfactory longitudinal studies We know that partial thrombotic venous occlusions do resolve if treated early with anticoagulants, but it is not known whether the superior vena cava ever recanalizes after complete thrombotic occlusion. Refinements in isotope venography have put its diagnostic accuracy virtually on a par with contrast studies and its reliability in the diagnosis of catheter-related thrombosis has been established[82] This should permit repeated assessments of the venous system to study both the natural history of venous thrombosis and to identify a group of patients in whom full anticoagulation would be desirable.

Catheter occlusion

The incidence of catheter occlusion varies widely. A catheter may become occluded by blood clot, fatty deposits or calcium salts. Usually, fatty deposits consist of layers of lipid derived from the infused solutions A particularly high occlusion rate has been observed in association with the use of 'all in one' mixtures containing fat[83–85]. It has been postulated that the lipid particles coalesce and enlarge in certain circumstances when lipid emulsions are mixed with other solutions in a 'big bag' and tend, as a result, to precipitate onto the catheter. Catheter occlusion is much less frequent when lipid is administered separately from other nutrients[86] A case has been reported where biochemical analysis of the fatty material occluding a catheter showed it to consist of lipids derived from blood lipoproteins or cell membranes presumably due to reflux of blood into the catheter[87] However, only a single occluded catheter was studied and similar findings have not been reported by others.

Occlusion of a catheter can be prevented by ensuring that neither blood nor nutrient solution is allowed to stagnate within it for any length of time. If blood is drawn through the catheter, it must afterwards be flushed with a solution of heparin–saline. Nowadays parenteral nutrition commonly is given intermittently, usually during a 12-h period overnight, the catheter being 'locked' with heparin during the daytime This regimen, originally introduced to free the patient of the paraphernalia of parenteral nutrition during daytime, has almost certainly had the added bonus of reducing the incidence of catheter occlusion There is also some evidence that the addition of 1–3 units heparin to every millilitre of infusion solution (originally suggested as a prophylaxis for catheter infection[56]) may reduce the incidence of occlusion Non-refluxing catheters which do not need to be heparin locked are available and will prevent thrombotic occlusion but will still be prone to occlusion from deposition of lipid unless flushed[88]

Forceful flushing may easily rupture a blocked catheter and therefore the only safe solution for a totally blocked catheter is to replace it In most cases, however, occlusion is not sudden but is manifested by the need for ever-increasing pressure to maintain a satisfactory infusion rate An early sign of impending occlusion is the inability to aspirate blood through the catheter despite satisfactory infusion of fluids[89] In such cases, locking the catheter with a solution containing 5000 units urokinase is often successful[90]. The procedure can be repeated after 24 h if unsuccessful since the small dose of urokinase causes no serious coagulation abnormalities. Should fibrinolytic therapy fail, it may be worth flushing the catheter with 0·1 M HCl in case the occluding material consists of insoluble calcium salts[91].

The incidence of catheter occlusion can be minimized by adopting the preventive measures described above and indeed many patients have been on home parenteral nutrition for years without experiencing an episode of catheter occlusion.

Endocarditis and intracardiac thrombi

A literature search found only three published reports of catheter-related endocarditis[80,92,93]. Almost certainly there must be other reported cases but even if the actual number was ten times higher, it would still be surprisingly small considering that a catheter tip situated in the right atrium, and perhaps even abutting on the tricuspid valve, must present an ideal situation for seeding of the valve should the catheter become infected.

It is quite likely that catheter-related endocarditis is much more common than is appreciated and that repeated episodes of septicaemia in an individual are often ascribed to new episodes of catheter infection or to infection from some other known source of sepsis without the diagnosis of endocarditis ever being considered A post-mortem examination of a patient who died of recurrent septicaemia at Hope Hospital while on home parenteral nutrition showed unsuspected endocarditis with widespread metastatic abscesses.

Recently a number of cases of right atrial thrombus have been described. One patient who presented with features of a pulmonary embolus and sepsis was found to have a right atrial thrombus requiring surgery[9]. Another was noted to have a pansystolic murmur and calcification in the region of the right atrium on X-ray. Echocardiography confirmed a right atrial mass prolapsing into the right ventricle which was subsequently removed[10]. The condition has also been described in infants[6,7,94] and it may be fatal[8]. Like venous thrombosis, right atrial thrombi are probably often silent and may therefore be more prevalent than is appreciated Reed and colleagues have attempted to determine the natural history of this condition[95]. They noted superior vena caval or intracardiac thrombi at autopsy in 17 per cent of their leukaemic patients who died with functioning catheters and without any symptoms or signs of central venous thrombosis. The majority of thrombi were nodules measuring 1–2 cm in diameter attached firmly to the walls of the cava or the heart. Interestingly, although thrombi were most frequently found in patients who had had a catheter for at least 5 months, no thrombi were noted in cases where the catheter had been in place for more than a year

What is the fate of intracardiac thrombi? Mendoza and colleagues have reported two cases in infants where removal of the catheter and anticoagulation resulted in the complete resolution of large intracardiac thrombi over a period of 6 months[94]. The situation may not be as encouraging in the adult, for the 'resolution' of thrombi in the infant heart may be partly explained by the enlargement of the chambers with normal growth thereby making the attached thrombi appear to be decreasing in size

Research is urgently required in this direction because of the potentially fatal outcome of endocarditis and intracardiac thrombosis As yet there are few clues pointing to the aetiology. It has been suggested that the infusion of hyperosmolar dextrose solutions and the positioning of the catheter tip in the superior vena cava rather than in the right atrium may play an important part in the genesis of right atrial thrombosis[10] but detailed studies are awaited. Surveillance by echocardiography should now become routine in any patient on long-term parenteral nutrition[96] but care must be taken to avoid misinterpretation of echograms by artefacts projected by the catheter tip[92].

New developments

Currently most research is being directed towards developing less thrombogenic catheters and vascular access devices which are totally implantable.

It is now recognized that catalysts and stabilizers used in the manufacture of catheters are just as important in determining the thrombogenicity of a catheter as the material from which the catheter is made. Catheters made from new materials based on polytetramethylene ether glycol are being evaluated. They do not contain any stabilizers or catalysts and become extremely flexible at body temperature. Laboratory studies have shown that such catheters exhibit a lower affinity than Silastic catheters for platelets[97]. Another approach to reducing catheter thrombogenicity is to coat it with a hydrophilic polymer. The polymer swells by drawing water from the bloodstream and is claimed to have a low affinity for platelets both in laboratory tests and when implanted in animals (data from CardioSearch, Tampa, Florida, USA). The results of long-term clinical studies of its use are awaited.

The most commonly used totally implantable vascular access device in the UK is the Port-a-cath® (Pharmacia Ltd., Milton Keynes, UK). Although primarily intended to facilitate intravenous chemotherapy[98], Baptista and colleagues have successfully used it for parenteral nutrition for over a year in one patient[99]. The author's experience is less favourable. All four patients into whom the Port-a-cath was implanted for home parenteral nutrition found it unsatisfactory. Patients found that access to the portal by puncturing the overlying skin was both difficult and painful, demanding greater dexterity than was required for a conventional catheter. In two cases there was marked displacement of the catheter tip after satisfactory initial positioning with consequent axillary thrombosis in one. This propensity for tip displacement and a high incidence of central vein thrombosis associated with the use of the Port-a-cath has been reported by others[100,101]. I have therefore abandoned the use of this device for parenteral nutrition until devices more suitable for use with parenteral nutrition become available.

Conclusions

Many catheter-related complications are avoidable with careful attention to technique, both of insertion and subsequent use. Much needless morbidity and mortality can thus be avoided. It is now well established that the complication rate can be minimized if experience is concentrated in the hands of a few dedicated individuals forming a nutrition team.

In patients with difficult vascular access, careful planning and special expertise are essential and such cases should therefore be referred to specialist centres. More research is required into the pathophysiology of venous and right atrial thrombosis. In the meantime, patients on long-term parenteral nutrition should undergo regular isotope venography and echocardiography to identify problems at an early stage.

Acknowledgements

I am grateful to Professor Irving and the staff of the Nutrition Unit at Hope Hospital for providing me with valuable experience in the field of parenteral nutrition. I would like to thank Lesley Lovell of Vygon UK for her assistance with the literature search and Professor Irving for his helpful comments during the preparation of the manuscript.

Multiple authorship

The Editors remain concerned about the number of papers submitted to the Journal which appear to carry an inappropriate number of authors. We whole-heartedly endorse the recent statement by the International Committee of Medical Journal Editors, namely that authorship 'should be based only on substantial contributions to (a) conception and design, or analysis and interpretation of data; (b) drafting the article or revising it critically for important intellectual content; and (c) final approval of the version to be published'. It must be stressed that these three criteria must *all* be fulfilled. Those submitting material to *The British Journal of Surgery* should be warned that the Editors intend to try to enforce these guidelines wherever possible.

Femorofemoral bypass in unilateral iliac artery occlusion

Between January 1973 and January 1988, 188 patients with unilateral iliac artery occlusion were treated at The Middlesex and University College Hospitals, 185 for primary disease and three for blockage of a previous aortobifemoral graft. In the early part of the series, a variety of operations, including aortofemoral and iliofemoral bypass, and endarteriectomy, was used. Femorofemoral bypass was at first reserved for patients who were considered unfit for major surgery, but the results seemed so good that it was adopted as the procedure of choice. Latterly, percutaneous transluminal angioplasty became available, and the role of this is discussed. Over the 15-year period, 150 patients underwent femorofemoral bypass (all but two receiving a prosthetic graft). Of these, 90 per cent had disabling claudication and 8 per cent had critical ischaemia. There were six early deaths (within 30 days of operation) and five late deaths, and two surviving amputees; nine patients could not be traced. The remaining 128 patients have been assessed at intervals of from 3 to 92 months, both clinically and with Doppler studies. The cumulative patency was 86 per cent at 13 years, and all of these patients experienced subjective and haemodynamic improvement in the recipient limb. Eight grafts occluded in the early postoperative phase. In five patients there was deterioration in the donor limb; it is postulated that the effect was due to causes other than the operation. There were two serious postoperative complications due to technical error, one of which led to early above-knee amputation. These are presented in detail. In the light of this experience, the advantages and indications for femorofemoral bypass and the results to be expected from it have become clarified, and the technique standardized so that errors can be avoided. We suggest that femorofemoral bypass is now the operation of choice for unilateral iliac artery occlusion.

The patient who presents with whole leg claudication due to unilateral iliac artery occlusion can be offered several treatment options including percutaneous transluminal balloon angioplasty, aortofemoral, iliofemoral or axillofemoral bypass, or varieties of endarteriectomy. The results of treatment for occlusions in these major vessels are on the whole good, in contrast to those obtained in the femoropopliteal segment. Most surgeons would treat a stenosis (as opposed to a complete occlusion) in this area by percutaneous transluminal angioplasty, which is simple and cost-effective, but at the same time would prefer open surgery in the case of complete occlusion. The simplest operation available is the femorofemoral bypass, originally described by Qudet and Beaconsfield in 1953[1]. In 1962 Vetto reported the first successful series of ten cases of unilateral iliac occlusion treated by this technique[2]. Initially the operation was reserved for poor-risk patients in whom intra-abdominal surgery was contraindicated[3], but the long-term results were surprisingly good and in 1983 our group reported an initial series of 66 patients[4]. We now present our definitive experience of the operation over 15 years.

Patients and methods

A total of 188 patients with unilateral iliac artery occlusion were treated at The Middlesex and University College Hospitals, London, between January 1973 and January 1988. Of these, 150 received a femorofemoral bypass, all but two receiving a prosthetic graft. There were 107 men and 43 women (71 and 29 per cent respectively). The age range was 42–82 years, with a median of 63. The symptoms requiring surgery were disabling claudication in 90 per cent, critical ischaemia according to the 1976 definition[5] in 8 per cent, and established gangrene in 2 per cent. Twenty patients (13 per cent) gave a previous history of myocardial infarct, angina or stroke. There were ten (7 per cent) diabetics in the series and nine (6 per cent) non-smokers. Of the 150 patients, 16 (11 per cent) had undergone previous aortoiliac surgery, including endarterectomy ($n = 8$), aortofemoral bypass ($n = 3$) or iliofemoral bypass ($n = 5$) which had been followed by reocclusion.

Patients were selected because of predominantly unilateral symptoms, confirmed by an absent or grossly weak femoral pulse on the affected side and a strong femoral pulse on the other side. Some of the patients in the early part of the study had stenoses rather than complete occlusions, and today would be managed by percutaneous transluminal angioplasty.

One advantage of this operative policy is that angiography is not always necessary. Retrograde (Seldinger) catheterization was carried out in 127 patients (85 per cent), but the combination of an absent femoral pulse and a viable limb is, for practical purposes, proof that the main upper channel of arterial supply, i.e. the profunda artery, remains open and is available for reconstruction.

Occlusion of the superficial femoral artery was not regarded as a contraindication to reconstruction either on the donor or the recipient side. In this series 20 patients (13 per cent) had an occluded superficial femoral artery on the symptomatic limb and five (3 per cent) had occlusion on the non-affected (donor) side. The arteries were blocked on both sides in three patients (2 per cent).

Pre- and postexercise Doppler ankle pressures were measured in all patients before surgery, immediately before discharge from hospital, and at each follow-up visit to the vascular clinic. The significance of differences were assessed by Student's t test and χ^2 analysis (with Yates' correction) as appropriate. Cumulative patency rates were determined by the modified life table method and results are expressed as mean ± s.d.

Operative technique

At induction of anaesthesia 1·5 mg cefuroxime and 500 mg metronidazole were given, and repeated for two postoperative doses at 12 and 24 h postoperatively. The bladder was catheterized for 48 h.

With the patient positioned supine, the legs abducted, the catheter in place, and both groins prepared, short vertical incisions were made over the femoral bifurcations, taking care to avoid the lymphatics and saphenous nerves; the arteries were then mobilized and controlled An appropriately sized graft (in practice usually 8–10 mm) was then preclotted using the Sauvage technique, involving successive passages of blood and thorough irrigation with concentrated heparin

Our preferred technique is to place the graft behind the rectus abdominis muscle This gives a shorter and more direct route, and the prosthesis is protected from external pressure This route is contraindicated if the patient is very obese or has undergone previous pelvic surgery or radiotherapy (as was the case in six of our patients) There is no difficulty in developing this tunnel by blunt finger dissection, and the prepared tube can then be drawn from one incision to the other using a long aortic clamp (*Figure 1*)

After systemic heparinization, simultaneous anastomoses were carried out between the graft and the donor and recipient arteries It is attractive to have the tube lie in a 'lazy S' form, following the direction of blood flow but, in practice, it is often easier to place it horizontally (*Figure 2*), and this has no effect on subsequent performance[6] In our series there were 90 right-to-left grafts (60 per cent) and 60 left-to-right grafts. If the origin of the superficial femoral artery was occluded, the profunda branch was used as the recipient vessel, as was the case in six patients. In a further seven cases a profundoplasty was required Pressure was recorded in the donor and recipient vessels before and after graft placement, and abolition of the gradient was confirmed (*Table 1*)

Postoperatively, mobility was encouraged, two further doses of antibiotic were given at 12 and 24 h, and the urethral catheter was removed on the morning of the second day Most patients were able to leave hospital within 1 week of surgery.

Results

Of the 150 patients, six died within 30 days of operation (see below), five died after this period, and there were two surviving amputees (see below). Nine patients were lost to follow-up The remaining 128 patients have been assessed at intervals of from 3 months to a mean of 92 months.

Immediate morbidity and mortality

Eight elderly patients with rest pain and gangrene developed graft occlusion within 4 weeks of operation. All of these were high-risk patients with past histories of myocardial infarction and hyperlipidaemia whose preoperative Doppler pressures had been <40 mmHg. After amputation six of these patients died, the causes of death being pulmonary embolus, myocardial infarction and bronchopneumonia.

Four patients developed a chest infection, and local complications comprised two deep vein thromboses, four lymphatic fistulae (all of which healed spontaneously) and one wound infection. In one patient, who had received radiotherapy some years previously for carcinoma of the cervix, the graft eroded an adherent loop of small bowel, and the resulting faecal fistula and sepsis eventually led to removal of the graft and an above-knee amputation (we would now regard such a history as a total contraindication to femorofemoral bypass) One 77-year-old man had undergone a previous retropubic prostatectomy and his graft was (mistakenly) placed in the cave of Retzius. Apart from superficial inflammation of the wound his postoperative recovery was uneventful and he left hospital with good femoral pulses and relief of symptoms. He was referred to a urologist 3 months later because of frequency of micturition, and at the subsequent cytoscopy the graft, still pulsating, was seen to have eroded through into the bladder. The urine was sterile and the bladder was reconstructed behind the undisturbed graft, which continued to function thereafter.

final assessment in 110 of the available 128 patients (86 per cent). Five patients out of the total series reported deterioration in the donor limb, all due to progression of their distal disease, and of these three required an amputation following closure of their femoropopliteal reconstruction. One patient underwent amputation of the recipient limb as a result of distal occlusion.

Patency rates. The cumulative patency at final assessment of the 128 available patients was 86 per cent No relation was noted to the sex of the patient, or to the side of the occlusion. All the patients who occluded their grafts had continued to smoke, and all had occlusion of the femoropopliteal segment on the recipient limb. The ankle systolic pressure on the affected side was <40 mmHg in all 15 cases. Three of them had undergone previous surgery for iliac occlusions.

Doppler pressure readings The preoperative Doppler pressures and ankle:brachial indices showed significant differences between the donor and recipient limbs, both at rest and after exercise ($P < 0{\cdot}05$). This gradient was abolished at the time of operation in all but the 15 patients who subsequently occluded their grafts. Of the others, there was significant improvement in the pressure in the recipient limb in 115 (90 per cent). Apart from the cases mentioned above, there was no deterioration in Doppler pressures on the donor side, either at early or late follow-up though, not unexpectedly, the preoperative ankle pressures on the donor side were lower in the patients with critical rather than severe ischaemia (*Table 2*).

Discussion

Although 25 years have passed since the original description of femorofemoral bypass[1], doubt is still sometimes expressed regarding the long-term patency and the effects on the donor limb[7]

The main attraction of the operation lies in its speed and simplicity, and the avoidance of intra-abdominal surgery in these often poor-risk patients. The operation is within the ability of any surgeon trained in basic vascular techniques and can if necessary be carried out under local anaesthesia[8] Although preoperative arteriography is useful in detecting proximal disease on the donor side, it can be dispensed with if the physical signs are clear-cut. A painful ischaemic leg with an absent femoral pulse, but with an easily felt pulse on the other side, usually predicts a satisfactory gradient We have previously reported[4] that an intraoperative gradient <25 mmHg indicates probable failure of femorofemoral bypass, and we would now carry out an iliofemoral or aortobifemoral bypass in such a case.

Our present policy is to perform Doppler pressure studies and a retrograde Seldinger aortogram and, if an iliac stenosis is found on the symptomatic side, to carry out a balloon angioplasty. In the presence of a complete occlusion, or if the angioplasty fails, the patient is entered on the next day's operating list for femorofemoral bypass.

Although femorofemoral bypass was originally reserved as a 'last ditch' operation for limb salvage in patients who were for some reason considered unfit for aortoiliac surgery, many surgeons, including ourselves, feel that the long-term results of this simple operation make it the procedure of first choice for patients with unilateral iliac occlusion who fulfil the usual criteria for surgical treatment. Given that the operation is safe and simple, its usefulness must be assessed by its complication rate (especially as regards the effect on the donor limb) and its long-term effectiveness. It is perhaps worthwhile to observe that 'long term' in this group of elderly and high-risk patients may involve periods of less than the conventional 5 years.

In general, the long-term results are satisfactory Harris *et al.*[9] reported a cumulative patency rate of 86 per cent at 4 years, which is identical to our own 14-year figure. Blaisdell *et al* [10] recorded a 2-year patency of 80 and 50 per cent, according to whether or not the distal arterial tree was occluded. Eugene *et al* reported a 30 per cent patency rate at 6 years[11] Apart from this last series, the figures suggest that femorofemoral bypass is at least equal in performance to major aortoiliac surgery[12].

The actual material used for the graft is probably not very important[13,14]. Our personal preference is for knitted material, for ease of preclotting. Morbidity and mortality rates are not easily compared because of unavoidable differences in case selection.

One considerable advantage of the femorofemoral bypass technique is the avoidance of the peri-iliac sympathetic plexus, disturbance of which may lead to erectile impotence[15,16] Indeed, the operation has been recorded as having a place in the restoration of penile blood supply[17]

Initial fears of a 'steal' phenomenon from the donor limb have not been realized. The study by Trimble *et al* [18], who reported two out of eight patients developing severe ischaemia in the donor limb, was not confirmed in an experimental study, nor in our own study (see above). The results of Harris *et al* [9], who reported a diminution in both exercise tolerance and ankle: brachial pressure indices, are also unconfirmed by our work, which agrees with the study of Dick showing that ankle:brachial ratios in the donor limb are unchanged after femorofemoral bypass[19]. There is also no evidence to support the suggestion that femorofemoral bypass potentiates disease in the donor side because of decreased flow

We conclude that femorofemoral bypass is simple, safe and effective in both the long and short term, and should be adopted as the procedure of first choice in patients with unilateral iliac artery occlusion who fulfil the accepted criteria for surgical relief.

Risk of aortic aneurysm surgery as assessed by preoperative gated heart pool scan

J. P. Fletcher, V. F. Antico*, S. Gruenewald* and L. Z. Kershaw

*Departments of Surgery and *Nuclear Medicine, Westmead Hospital, Westmead, New South Wales, Australia 2145*

Correspondence to:
Mr J. P Fletcher

Gated heart pool scan measuring left ventricular ejection fraction (LVEF) was performed preoperatively in 72 patients presenting for elective repair of abdominal aortic aneurysm. Patients with a positive cardiac history were more likely to have a LVEF of $\leqslant 45$ *per cent* ($P<0\cdot001$)*. The operative mortality rate was 4 per cent. Each of three patients who died had a LVEF* $\leqslant 35$ *per cent and developed cardiac failure which led to renal failure. Five other patients developed cardiac failure manifested by acute pulmonary oedema during the early postoperative period. There was no statistically significant association between a positive cardiac history and the occurrence of postoperative cardiac failure or death. However, patients with a LVEF of* $\leqslant 45$ *per cent were more likely to develop postoperative cardiac failure* ($P=0\cdot004$) *while patients with a LVEF of* $\leqslant 35$ *per cent had a greater chance of dying* ($P<0\cdot001$)*. No patient died with a LVEF* >35 *per cent. Preoperative evaluation of LVEF can select patients at high risk of cardiac death from repair of abdominal aortic aneurysm. Such patients could be followed conservatively if they remain asymptomatic and the aneurysm does not enlarge. If operation is considered mandatory, patients with a low LVEF should receive intensive perioperative monitoring with enhancement of ventricular performance.*

Keywords: Aortic aneurysm repair, gated heart pool scan, left ventricular ejection fraction

The most frequent complication likely to lead to death following surgical repair of an abdominal aortic aneurysm is cardiac failure. Cardiac complications occur with greater frequency in patients known to have pre-existing coronary artery disease which may be evident from a history of previous myocardial infarction, angina or cardiac failure. However, some patients with significant coronary artery disease remain asymptomatic, and an additional investigation is required to identify patients at increased risk of death from cardiac complications following repair of abdominal aortic aneurysm.

From 1985, it has been our practice to obtain a gated heart pool scan preoperatively in patients presenting for elective repair of an abdominal aortic aneurysm. The purpose of this study was to assess the usefulness of this investigation in patients having aortic reconstruction for aneurysm disease.

Patients and methods

There were 72 consecutive patients studied over a 2-year period comprising 57 men and 15 women. Their ages ranged from 38 to 81 years with a mean age of 67·7 years (s.d. 7·4 years).

The presence of heart disease (history of myocardial infarction, angina, cardiac failure or abnormal ECG) was recorded for each patient and scored as 0 for no evidence of heart disease, 1 for previous history but currently asymptomatic, and 2 for symptomatic at the time of presentation.

Gated heart pool scan was performed preoperatively in the Department of Nuclear Medicine. Technetium-99 (^{99m}Tc) labelling of autologous red blood cells was performed by a modified *in vivo* method[1,2]. Stannous pyrophosphate was injected intravenously; 20 min later, 4 ml blood was withdrawn into a heparinized syringe containing 900 MBq ^{99m}Tc. This was then injected as a bolus after 10 min incubation. The patient was positioned supine under a small field of view γ camera which was rotated to the left anterior oblique position that best separated left and right ventricles. Data were entered onto a dedicated computer with 24 frames on a 64×64 matrix. At least 4×10^6 counts were acquired. Left ventricular ejection fraction (LVEF) was calculated by identifying the end-diastolic and end-systolic images. A region of interest was drawn around the left ventricle in each of the images, with a further region drawn to represent background[3,4]. LVEF equals end-diastolic counts minus end-systolic counts divided by end-diastolic counts. All counts were corrected for background. The normal range for LVEF in our department is 55–75 per cent.

All patients had a radial artery catheter inserted for perioperative monitoring of blood pressure which was kept as close to the preoperative level as possible by fluid and blood administration as required; nitroprusside was required in 10 patients at the time of aortic cross-clamping to control severe hypertension.

Postoperative course was recorded for each patient and scored as 0 for no cardiac complications, 1 for a cardiac complication from which the patient recovered, and 2 for death.

Data were entered into a microcomputer and analysed by Human Systems Dynamics (Northridge, California, USA) program using χ^2 analysis, Student's *t* test and multiple regression analysis.

Results

Of the 72 patients, 36 (50 per cent) had no history of cardiac disease, six (8 per cent) had a previous history but were currently asymptomatic and 30 (42 per cent) had symptoms of angina or cardiac failure at the time of presentation with their aneurysm (*Table 1*). LVEF ranged from 25 to 86 per cent with a mean of

Table 1 *History of heart disease related to left ventricular ejection fraction*

Currently symptomatic	30	2	3

Table 3 *Postoperative cardiac failure related to left ventricular ejection fraction*

	LVEF$\leqslant$45%	LVEF>45%
Cardiac failure	5	3
No cardiac failure	11	53

LVEF, left ventricular ejection fraction. Postoperative cardiac failure was more likely when preoperative LVEF $\leqslant$45 per cent: χ^2 8·45, P=0·004

56·1 per cent (s.d. 15·3 per cent). There was a strong association between cardiac history and LVEF (*Table 1*); patients with a positive cardiac history were more likely to have a LVEF of $\leqslant$45 per cent (P<0·001). A straight woven Dacron® (E. I. Dupont de Nemours Inc.) graft was used in 49 patients (68 per cent) and a bifurcated graft in 23 (bi-iliac graft in 21, bifemoral graft in two). There were three postoperative deaths—an operative mortality of 4 per cent. All three patients died from cardiac failure leading to renal failure. Five other patients developed cardiac failure manifested by acute pulmonary oedema during the early postoperative period (*Table 2*). There was no statistically significant association between cardiac history and the occurrence of postoperative cardiac failure or death.

There was no association between requirement for intraoperative nitroprusside administration for control of hypertension and the occurrence of postoperative cardiac complications.

Patients with a preoperative LVEF of $\leqslant$45 per cent (*Table 3*) were more likely to develop postoperative cardiac failure (P=0·004) while patients with a LVEF of $\leqslant$35 per cent (*Table 4*) had a greater chance of dying (P<0·001). No patient died with a LVEF >35 per cent.

Multiple regression analysis was performed using outcome as a determinant factor, and cardiac history and LVEF as predicting factors. Cardiac history was not a significant predictor (P=0·44) but LVEF was significant at predicting death and cardiac failure (P=0·01).

Discussion

Coronary artery disease is common in patients with abdominal aortic aneurysms and is the most frequent cause of operative mortality and later death in patients surviving surgery[5–8].

Advances in perioperative care have reduced the operative mortality of elective aneurysm repair, although late survival rates have remained constant[8,9]. Some investigators have performed haemodynamic studies to try to identify patients with abnormal cardiac function who would be at increased risk of developing postoperative cardiac complications. Pulmonary artery catheterization has been used preoperatively to measure cardiac output, cardiac index, right and left ventricular stroke work, and systemic and pulmonary vascular resistance. In one study in patients having elective vascular surgery, only 33 per cent of patients had normal left ventricular function[10]. Maintenance of optimal cardiac index during the perioperative period has been shown to reduce the incidence of postoperative cardiac complications in patients having repair of abdominal aortic aneurysm[11].

Died	3	0
Survived	7	62

LVEF, left ventricular ejection fraction. Patients with a preoperative LVEF$\leqslant$35 per cent were more likely to die: χ^2 19·41, P<0·001

Routine preoperative pulmonary artery catheterization is impractical at our institution because of pressure on intensive care beds. Furthermore, it is not possible for all patients to be managed routinely in intensive care postoperatively. It is therefore important to identify patients especially at risk of postoperative cardiac complications so that intensive care facilities can be made available for this group while patients at less risk bypass the intensive care ward.

The presence of coronary artery disease can be assessed by careful history and management decisions made accordingly[12,13], but in our study history alone was not significant in predicting the risk of cardiac complications developing postoperatively.

Stress electrocardiography is often used as a non-invasive screening test to select patients for coronary angiography. However, false positive rates of 16–40 per cent and false negative rates of 15–33 per cent have been encountered with some 24 per cent of patients being unable to complete the exercise testing because of claudication or dyspnoea[14,15]. The incidence of false negative stress electrocardiography may be greater when there is a high prevalence of coronary artery disease in the population being tested[16], such as would be the case in patients presenting with aortic aneurysm.

Routine screening of all patients presenting for vascular reconstructive procedures with coronary angiography has been performed [17], but is invasive and is not practical for most institutions.

Non-invasive radionuclide assessment of cardiac function by measurement of LVEF[18] is useful for identifying patients at increased risk of developing postoperative cardiac complications. Methods other than gated heart pool scan are available and involve use of M-mode and two-dimensional echocardiography with or without Doppler[19–22]. However, not all patients can be imaged successfully owing to limited access to the heart because of over-expanded lung fields, a problem frequently encountered in patients with cardiovascular disease who have an increased incidence of chronic obstructive airways disease. Successful examination is possible in only some 84 per cent of patients[21]. In our series, no patient was excluded because of inadequate gated heart pool scan.

Ideally, LVEF should be combined with an assessment of coronary artery status; we are currently investigating the usefulness of dipyridamole thallium scanning for detecting the presence of significant coronary artery disease in patients undergoing arterial reconstruction.

Our findings of increased risk of cardiac complications occurring in patients with a low ejection fraction are in agreement with those of Fiser *et al.*[23] and Mosley *et al* [24]. We support their conclusions that preoperative evaluation of ejection fraction can select patients at high risk of cardiac death following abdominal aortic operation. Such patients can be followed conservatively if asymptomatic[25], or, if surgery is considered essential, intensive perioperative monitoring with enhancement of ventricular performance is recommended.

A study of plasma arginine vasopressin (AVP) levels and their relation to changes in arterial pressure was undertaken in 13 patients undergoing open heart surgery. Seven of the patients received high doses of intravenous morphine (1 or 2 mg/kg) as part of their anaesthetic, whereas the other six did not. Increases in the AVP levels during cardiopulmonary bypass (CPB) were significant in both groups, but were significantly greater in the patients not receiving morphine (median 86·1 fmol/ml) than in those who did (47·5 fmol/ml). In both groups there was a linear correlation between the natural logarithm of the plasma AVP level and the percentage fall in the mean arterial pressure, although the slope of the relationship was significantly less in the group receiving morphine than in the group not receiving morphine. These results indicate that in patients undergoing cardiac surgery the neuroendocrine reflex control of plasma AVP levels in relation to changes in arterial pressure is intact, but that the sensitivity of the reflex (i.e. the increase in plasma AVP level for a given fall in arterial pressure) is reduced by the administration of high doses of intravenous morphine.

Keywords: Vasopressin, operative surgery, arterial pressure

In 1953 Le Quesne and Lewis[1] observed that after surgical operations not only was there a reduction in sodium excretion, but there was also a separate and specific defect of water excretion. They inferred that this was due to the secretion of increased amounts of arginine vasopressin (AVP). Subsequent measurements of plasma AVP levels both by bioassay[2] and by radioimmunoassay[3] have confirmed this. Studies in the anaesthetized human undergoing surgical operations have variously attributed different proportions of the increases in levels of the hormone to the fluid depletion of the overnight fast[4,5], preoperative anxiety[6], the induction and maintenance of anaesthesia[3], and changes in extracellular fluid volume[7]. The very high levels recorded during laparotomy[2], and sternotomy and cardiopulmonary bypass (CPB)[5] have usually been attributed to unquantifiable variables such as visceral manipulation[2], pain[4], or the magnitude of the operative trauma[3]. Philbin and Coggins[8] concluded that 'stress' was a stimulus to AVP release, from their observation that high doses of intravenous morphine prevented any rise in plasma AVP levels during open heart surgery in the period before CPB.

Studies in experimental animals and conscious humans[9] have clearly shown that not only is falling arterial pressure a potent stimulus to AVP release but also that the relationship between the two variables can be expressed mathematically. Cochrane *et al.*[10] suggested that falling arterial pressure might be an important stimulus in the anaesthetized subject, but there has been no formal study of the relationship between these two variables during surgical operations. This study was therefore designed to test the hypothesis that falling arterial pressure is an effective stimulus to AVP release in patients undergoing surgical operations. Patients undergoing open heart surgery were chosen because of the large changes in arterial pressure often associated with these operations and the small changes in plasma osmolality, which thus tended to isolate the arterial pressure as a possible stimulus, and because of the comparative ease of obtaining a continuous record of the arterial pressure and frequent blood samples. Seven of the patients were given high doses of intravenous morphine in the light of its inhibitory effect on AVP levels, as demonstrated by Philbin and Coggins in similar patients[8].

Patients and methods

Studies were performed on 13 patients who underwent a variety of cardiac operations, all requiring the use of CPB. Patients in atrial fibrillation were excluded, as were children, in whom the sampling volumes would have been unacceptably high, and patients deemed by the anaesthetist to be unsuitable candidates for the high dose intravenous morphine regimen. Suitable patients (i.e. those in whom either anaesthetic technique was equally acceptable) were then randomly allocated to one of two groups: those receiving morphine (MORPH) or those not receiving morphine (NOMORPH). There were six patients in the NOMORPH group, all of them men, with an average age of 49·2 years (range 34–61). Three of them underwent coronary artery bypass grafting and three aortic valve replacement. There were seven patients in the MORPH group, six men and one woman with an average age of 58·6 years (range 49–66). Four of these patients underwent coronary artery bypass grafting, two underwent aortic valve replacement and one had a resection of a left ventricular aneurysm. All the patients having coronary artery bypass grafting were receiving treatment for angina consisting of varying combinations of a β-blocker, nifedipine, and glyceryl trinitrate.

Premedication consisted of Omnopon (Roche Products Ltd., UK) or diamorphine and hyoscine, and anaesthesia was induced with thiopentone and pancuronium. Anaesthesia was maintained in the NOMORPH group with halothane, nitrous oxide, and oxygen. In the MORPH group, patients received either 1 or 2 mg/kg body weight morphine sulphate, given intravenously over approximately 3 min, shortly after the induction of anaesthesia which was supplemented with nitrous oxide and oxygen. During CPB, Althesin (Glaxo Laboratories, Middlesex, UK) and droperidol were also used in some patients.

Arterial pressure was measured continuously from a cannula placed in the radial artery immediately after induction of anaesthesia. This was connected to a pressure transducer (AE 840, A.M.E., Horten, Norway) and dome (AE 841, A.M.E., Horten), whose electrical output was fed to an SE 905 transducer/converter (S.E. Laboratories, Feltham, UK). The output from the latter was continuously displayed on a chart recorder (Gould Brush 220, Gould Medical UK, Lutterworth, UK). Arterial pressure recording before the insertion of the radial artery cannula and its connection to the recording equipment were carried out using Dinamap Adult Paediatric Vital Signs Monitor Model 845 (Kritikon, Tampa, USA), which was shown to correlate well with the direct radial artery measurement (correlation coefficient $r = 0{\cdot}98$, $n = 44$, $P < 0{\cdot}001$)). The blood pressure corresponding with each blood sample was recorded as the minimum mean pressure in the 10-min interval after the preceding sample (see below).

Mean*	0·57	0·063	

* Mean of a and b, for the equation $\ln[AVP] = b\Delta MP + a$ where ΔMP is the percentage change in mean arterial pressure

In order to allow direct comparison with the results of Robertson[9], the percentage fall in the mean arterial pressure (ΔMP) was calculated, and subsequently this value was used in all calculations. ΔMP was calculated in each patient as the percentage reduction from the maximum mean arterial pressure recorded for that patient following induction of anaesthesia

Blood samples of 6 ml were taken immediately before premedication, immediately before induction of anaesthesia, and thereafter every 10 min until the end of CPB The first two samples were taken from a peripheral vein, usually in the antecubital fossa Subsequent samples were taken from a catheter in the superior vena cava, placed via the internal jugular vein by direct skin puncture. Samples were immediately centrifuged and the supernatant removed One aliquot of this was put in dry ice and subsequently stored at −20°C to await AVP assay The other aliquot was used for the immediate determination of the plasma osmolality and the plasma protein concentration.

Plasma AVP levels were measured by radioimmunoassay, by a modification of the method of Forsling and Williams[11] The intra-assay coefficient of variation was 7·7 per cent and the interassay coefficient of variation 11·9 per cent. AVP levels during CPB were corrected to allow for the change in the volume of distribution of the hormone caused by the extracorporeal circulation. Under normal circumstances the hormone is thought to equilibrate with the extracellular fluid[12]. Since the pump-priming fluid was protein free, the AVP concentration during CPB was multiplied by the ratio of the plasma protein concentration immediately before instituting CPB and the plasma protein concentration immediately after instituting CPB Plasma osmolality was measured using the Knauer Halbmicro (Knauer, Heidelberg, FRG) freezing point depression osmometer Plasma protein concentration was measured using a table model clinical refractometer (Avap Optical Works Company Ltd , Tokyo, Japan

For comparison of AVP levels at different stages in the operation the samples were grouped together in six periods period 1, the time before premedication, period 2, after premedication and before induction of anaesthesia; period 3, after induction and before the initial skin incision, period 4 (only in those patients who had coronary artery bypass grafts), during the dissection of the long saphenous vein and before median sternotomy, period 5, from median sternotomy until the establishment of CPB, period 6, the time on CPB

Data were stored on a CDC Cyber 174 computer (Control Data, Minneapolis, USA), and statistical computation was carried out using the statistical software package MINITAB[13] AVP levels for different periods in the operation were compared using the Mann–Whitney *U* test Linear regression analysis was used to regress the natural logarithm of the plasma AVP concentration (ln[AVP]) against the ΔMP

All the patients gave their informed consent to the study, which was approved by the ethical committee of The Middlesex Hospital

Results

Changes in plasma AVP concentration

Table 1 shows the median plasma AVP concentrations in the two groups. There were no statistically significant changes over the levels in period 1 (NOMORPH 2·3 fmol/ml; MORPH 3·3 fmol/ml) in either group in periods 2, 3 or 4. The level in period 5 (after thoracotomy) reached 25·3 fmol/ml in the NOMORPH group which was significantly higher than the levels reached in the previous periods and higher than the level for the same period in the MORPH group (13·7 fmol/ml), the latter, however, was not higher than preceding levels in this same group. In period 6 (on CPB) the level in each group was significantly higher than in the premedication period, and the level in the NOMORPH group (86·1 fmol/ml) was significantly higher than that in the MORPH group (47·5 fmol/ml).

Percentage changes in mean arterial pressure

There were statistically significant falls in arterial pressure in period 6 (on CPB) in each group, and the fall was significantly greater in the NOMORPH group that in the MORPH group (*Table 1*).

Correlation of ln[AVP] with ΔMP

In the NOMORPH group there was a linear correlation between the plasma ln[AVP] and ΔMP *Table 2* shows the *y* intercept, the slope or regression coefficient and the correlation coefficient for each patient. The linear correlation is borne out by an inspection of scatter diagrams for individual patients (*Figure 1*). The same statistics for the MORPH group appear in *Table 3*. *P* values have not been calculated for these correlations in view of the tendency for serial correlation in the data from each patient owing to the sequential nature of the observations. However, it can be demonstrated that the regression coefficients for both the MORPH and the NOMORPH groups are positive and differ significantly from zero ($P < 0·05$, Wilcoxon signed rank test).

Comparing the regression coefficients in the two groups it can be shown that the slope for the NOMORPH patients is significantly steeper than that for the MORPH patients ($P < 0·01$, Wilcoxon signed rank test).

Changes in plasma osmolality

The changes in plasma osmolality (*Table 1*) were small and only reached significance between periods 5 and 6 in the NOMORPH group.

Discussion

The pattern of change in plasma AVP levels during the course of the operations in this study was consistent with previously published findings. Basal levels were within the normal 'unstimulated' range quoted by most authors (e.g Forsling and Williams[11]), and the lack of any significant change in plasma AVP levels in either group in periods 2 (before induction) and 3 (after induction) is consistent with the view that neither premedication[8] nor induction of anaesthesia[2,8] has any significant effect on plasma levels of the hormone. Similarly, the lack of any significant change in AVP levels during period 4, while the saphenous vein was being harvested, accords with the observations of Nashat[14] in the greyhound, although Moran *et al*[4] did record small rises in AVP levels during skin incision unless regional anaesthesia was used. The values obtained for period 5 (after median sternotomy) are in agreement with those of Philbin and Coggins[8] in that the levels in the group which received no morphine were significantly elevated (median 25·3 fmol/ml) whereas in the MORPH patients the levels, although elevated, were not significantly so. The explanation offered by Philbin and Coggins was that morphine was suppressing the stress response Simpson and Forsling[15], reporting similar findings, suggested the alternative explanation that the use of halothane might itself be associated with increased AVP levels. Others have found either no specific stimulation of AVP release by halothane[7,16] or have suggested that any increase in AVP levels associated with halothane was secondary to the cardiovascular effects of the drug[17] The evidence presented here tends to support the latter view in that not only was there a correlation with arterial pressure in both groups (i e those receiving halothane and those not receiving halothane), but also falls in arterial pressure were greater in the patients receiving halothane. Any specific stimulation of AVP secretion by halothane would therefore have to be separate from the effect of falling arterial pressure. The difference in the sensitivity or slope of the relationship (see below) between ln[AVP] and the fall in arterial pressure in the MORPH and NOMORPH groups of patients might have been an effect of the halothane in the NOMORPH group or the morphine in the MORPH group.

The findings in this study clearly show a correlation between the ln[AVP] and the ΔMP. This has not previously been reported in anaesthetized subjects undergoing surgical operations. It has previously been shown by Robertson[9] that in conscious human subjects rendered hypotensive with the ganglion-blocking agent trimetaphan there is a correlation between these two variables that is described by the equation:

$$\ln[AVP] = 0{\cdot}11\Delta MP + 0{\cdot}34$$

The equation for the NOMORPH patients in the present study, derived by taking the mean of the values for the intercept and regression coefficients from each patient, is.

$$\ln[AVP] = 0{\cdot}063\Delta MP + 0{\cdot}57$$

and that derived for the MORPH patients is:

$$\ln[AVP] = 0{\cdot}032\Delta MP + 1{\cdot}56$$

When plotted these equations describe the straight lines shown in *Figure 2.*

The demonstration of a correlation does not of itself imply a causal relationship between two variables. However, it is widely accepted that the relationship observed by Robertson[9], and described by the equation set out above, does imply a causal link between a fall in arterial pressure and a rise in the plasma AVP concentration, this relationship being dependent upon the functional integrity of the carotid sinus[18] and its nerve supply[19] The findings in the NOMORPH group that the relationship of the fall in arterial pressure to the AVP level and the slope of this relationship are similar to those found by Robertson in normal adults[9] strongly suggest that this causal

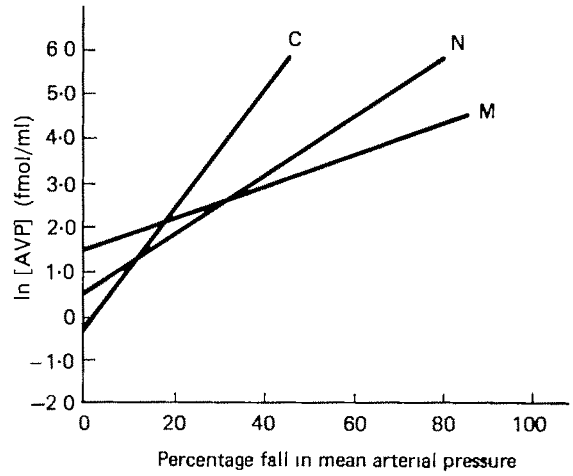

Figure 2 *Regression lines for the relationship ln[AVP] = bΔMP + a in the patients in the group receiving no morphine (N), and in the patients in the group receiving morphine (M), calculated from the mean values for* a *and* b *(Tables 2 and 3), and in conscious subjects (C Robertson[9]) ln[AVP], the natural logarithm of the median plasma arginine vasopressin concentration,* a, *y intercept,* b, *regression coefficient, ΔMP, the percentage fall in mean arterial pressure*

relationship is maintained during these operations The smaller value for the regression coefficient (a measure of the slope of the regression line) in this group of patients compared with the value obtained by Robertson may be interpreted as a reduction in the gain or sensitivity of the neuroendocrine reflex caused probably by one of the anaesthetic agents The still greater (and statistically significant) reduction in the regression coefficient in the MORPH patients may similarly be interpreted as a depressant effect of the morphine on the sensitivity of the reflex. This is consistent with, and may provide an explanation for, the observation of Philbin and Coggins[8] that high doses of intravenous morphine apparently inhibit the secretion of AVP There is much support for the view that opiates have a depressant effect on AVP levels, both when given systemically and by the intracerebroventricular route[20], although the traditional view[21] was that morphine stimulated the release of AVP. Reconciliation of this apparent paradox may have come from the observations of Aziz *et al.*[22] who have shown that the effect of intracerebroventricular morphine may be either inhibitory or stimulatory depending on the dose, the timing, and probably the state of hydration as well. Despite the balance of evidence from other sources it is not possible from the data presented here to refute the alternative hypothesis that the effect on the sensitivity of the reflex demonstrated here is due to an increase in gain or sensitivity caused by halothane in the NOMORPH group rather than to a reduction in sensitivity caused by the morphine in the MORPH group.

It is suggested that the relationship between plasma AVP level and falling arterial pressure is well seen in these patients because the large changes in arterial pressure swamp other possible stimuli to AVP secretion, in particular changes in osmolality, which were small, and the secretion which may be associated with pain[4], opening coelomic cavities[23], visceral traction, and other various operative stimuli

These results provide strong evidence that, in patients undergoing open heart surgery, the neuroendocrine reflex control of plasma AVP levels in relation to changes in arterial pressure is intact, but that the gain or sensitivity of the reflex is reduced by the administration of large doses of intravenous morphine. The pathophysiological logic of the graded secretion of one of the most powerful vasopressor substances known in response to a fall in arterial pressure is compelling It was perhaps naive to refer to this aspect of the endocrine response to surgical operations as the 'inappropriate' secretion of AVP

KING'S COLLEGE HOSPITAL
F.R.C.S. Revision Course
in
CLINICAL SURGERY
April 3rd – 14th, 1989

An intensive revision course designed for final FRCS candidates will be held at King's College Hospital over a period of 2 weeks. All major specialties will be covered as well as Oncology, Vascular, Urological, Hepato-Biliary and Orthopaedic surgery. Sessions on radiology, surgical pathology, operative surgery and clinical examination techniques are included. Lectures by visiting experts will be a feature of the course. Places will be limited and early applicatioin is advised.

Local accommodation can be arranged.

Application closing date – 13th March, 1989.

Course Fee: £260

Further details and application forms from:

Positioning the Surgical Patient

J. M. Anderton, FFARCS Consultant Anaesthetist, Manchester Royal Infirmary **R. I. Keen,** FFARCS Consultant Anaesthetist, Manchester Royal Infirmary **R. Neave,** FMAA Medical Artist, University of Manchester

★ Explains clearly the 'how' and 'why' of patient positioning. ★ Superb illustrations demonstrate all important positioning techniques. ★ Indispensable to anyone working in the operating theatre.

The correct positioning of the surgical patient is of vital importance to a successful outcome. Each type of operation demands that the patient be placed in a particular way, but for each position there are associated problems and risks. This is the first short textbook to explain the 'how' and 'why' of patient positioning, and it does so in a clear and comprehensive manner.

The authors use a carefully integrated mixture of text and line illustrations to describe the purpose of the main surgical positions. For each, they then cover in detail the associated anatomical hazards; the specific techniques required to achieve the correct position – illustrated with action sequences drawn from actual operative situations; and conclude with variants of the basic positions. A final chapter on respiratory and circulatory aspects highlights the physiological implications for the patient of the different positions.

Although precise details of practice vary from hospital to hospital, the authors concentrate on the principles rather than the minutiae. The result is a textbook which should have broad appeal to anyone with operative surgical responsibilities. This includes surgical and anaesthetic staff, who have the primary task of selection and general implementation of patient position, as well as nurses and operating department assistants who play an indispensable role in its detailed execution.

CONTENTS The supine position ● The lithotomy position ● The lateral position ● The prone position ● The sitting position ● The transfer of patients and recovery room practice ● Specialized positions ● Physiological effects of posture in the anaesthetised patient ● Index *March 1988 128 pages 246 x 189 mm Softcover 156 line illustrations 0 407 012206 £12.95*

GORE-TEX™ SUTURES

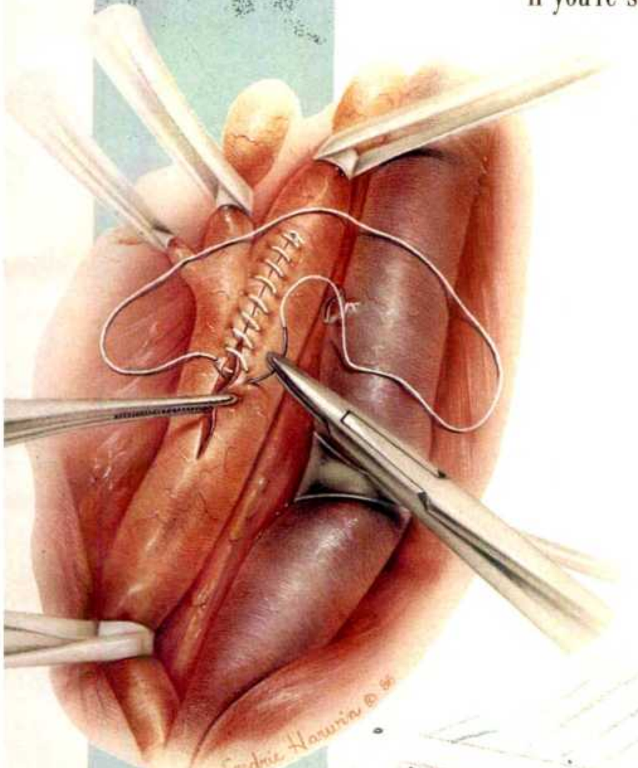
W L Gore & Associates has taken the first steps into the next generation of synthetic sutures:- sutures which easily outperform both polyester and polypropylene.

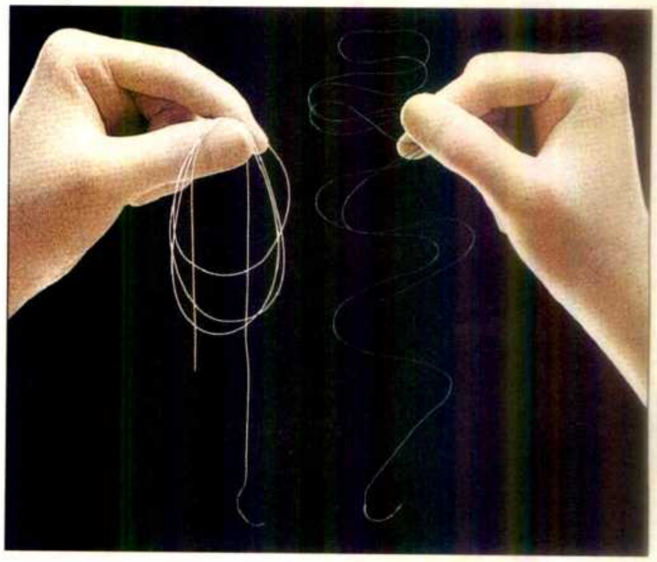
The GORE-TEX™ Suture is a porous, non-absorbable monofilament of Expanded PTFE that gives you precise knot placement, a high knotted tensile strength, and resistance to the spread of infection.

As for handling, PTFE has no 'memory', so it behaves like a silk suture. Expanded PTFE is totally inert and biocompatible. Its microporous structure means it can be incorporated by the surrounding tissues. That strengthens the suture line and helps resist the spread of infection, which can spread along the line of an encapsulated polypropylene suture.

If you're still not using the GORE-TEX™ Suture, it's time you made the move.

- Non-allergenic
- Non-inflammatory
- Biocompatible
- Does not degrade in the presence of infection.





The GORE-TEX™ Suture is soft and supple and shows no memory effect like other suture materials. This softness of the GORE-TEX™ Suture offers excellent handling properties.

™ GORE-TEX is a trade mark of W L Gore & Associates Inc.

CONCISE SYSTEM OF ORTHOPAEDICS AND FRACTURES

A. Graham Apley MB BS, FRCS, FRCSEd (Hon)
Consulting Orthopaedic Surgeon, St Thomas' Hospital, London. Emeritus Consultant Orthopaedic Surgeon. The Rowley Bristow Orthopaedic Hospital, Pyrford, and St. Peter's Hospital, Chertsey, Surrey. Editor, *Journal of Bone and Joint Surgery* (British Issue).

Louis Solomon MB ChB, MD, FRCS, FRCS(Ed)
Professor of Orthopaedic Surgery, University of Bristol. Formerly Professor of Orthopaedic Surgery, University of the Witwatersrand, Johannesburg.

- ★ **A shorter, revised version of the classic 'Apley's System'**
- ★ **Same systematic presentation – ideal for learning and revising**
- ★ **Nearly 500 illustrations, many presented as composites**
- ★ **Meets the needs of undergraduate and paramedical students**

Apley's System of Orthopaedics and Fractures has for long been an established favourite. But it is a textbook designed primarily for post-graduates, and for many readers it is unnecessarily detailed. This new *Concise System* is a distillation of the larger book and will meet the needs of those looking for an introductory account of modern orthopaedics.

With their customary clarity and style the authors present the basic principles of orthopaedics at a level suitable for undergraduates and paramedical students. By eliminating much of the detail and concentrating on basic principles they have produced a shorter and more succinct textbook. As usual much of the information is contained in the superb illustrations. Arranged as composites for greater effect, and with crisp and informative captions, they make rapid revision relatively easy and pleasurable.

Systematic, balanced and easy to use, the *Concise System* is an outstanding textbook of orthopaedics for anyone seeking a brief account of this large subject. It is also a natural precursor to the more detailed coverage of the subject offered by its larger parent.

Carotid body tumours and other cervical paragangliomas: diagnosis and management in 25 patients

G. A. D. McPherson, A. W. Halliday and A. O. Mansfield

Department of Vascular Surgery, St. Mary's Hospital, Praed Street, London W2 1NY, UK

Correspondence to:
Miss A. O. Mansfield

This report of a series of 25 patients with cervical paragangliomas reviews the experience of one surgeon over a period of 13 years. A total of 26 resections were performed with no mortality and no hemiplegia. Two patients required carotid reconstruction. Eight patients had a permanent cranial nerve palsy but in seven this was due to involvement of the nerve by the tumour. Lymph node involvement occurred in two patients. Only one patient has developed recurrent tumour. These tumours are locally malignant and resection offers a chance of cure.

Keywords: Cervical paraganglioma, diagnosis, management

The carotid body is a small chemoreceptor organ measuring 7 × 4 mm and lies buried in the adventitia in the posterior aspect of the common carotid bifurcation. First described by Haller[1] in 1743 it is now known to be involved in the reflex control of heart rate, blood pressure and respiration via the chemical composition of blood and its temperature and forms part of an extensive chemoreceptor system. Tumours of this tissue were originally described as chemodectomas by Mulligan (1950)[2] and the most common of these are carotid body tumours. These form part of a widely distributed group of tumours known as paragangliomas.

Carotid body tumours are rare (an incidence of 0·012 per cent of surgical specimens at one hospital has been reported)[3]. The diagnosis can present considerable hazards and inexperienced removal can be disastrous. Matthews observed in 1915[4] that 'this rare tumour presents unusual difficulties to the surgeon and should he encounter it without having suspected the diagnosis, the experience will not soon be forgotten.' This paper describes a series of 25 patients presenting over 13 years and examines trends in diagnosis and management.

The first successful excision of a carotid body tumour was reported by Maydl in 1886[5]. Unfortunately the patient was hemiplegic and aphasic after the operation. In 1889 Albert managed to excise a carotid body tumour without ligation of the carotid vessels[6]. However, a persistently high mortality rate for resection of carotid body tumours, around 30 per cent, led Martin *et al.*[7] to state in 1957 that these tumours should be subject to biopsy only. As recently as 1971, Shamblin *et al.*[8] from the Mayo Clinic reported 16 cerebrovascular accidents in 72 operative procedures, probably the largest published series, and as a result of this study they proposed a surgical classification of carotid body tumours as follows: group I, easy to remove from adjacent vessels; group II, intimate attachment to the carotid artery requiring dissection in the subadventitial plane[9]; group III, where there is transmural invasion of the carotid artery by the tumour. Approximately half of the tumours in their series fell into group II, the other half being distributed between groups I and III. More recently a pathological classification has been proposed by Glenner and Grimley[10]. Carotid body tumours and chemodectomas arising from the glomus jugularis and chemoreceptor tissue around the lung are grouped together in this classification and called the branchiomeric paragangliomas as opposed to the intravagal or aorticosympathetic paragangliomas. The distribution of branchiomeric paragangliomas is shown in *Figure 1*. Glenner and Grimley[10] have suggested that paragangliomas should be classified according to anatomical site and functional activity. Thus the precise nomenclature for a carotid body tumour is 'carotid body paraganglioma non-functional'. Paragangliomas may occur synchronously in about 10 per cent of patients and while carotid body tumours are not functionally active, other branchiomeric and aorticosympathetic paragangliomas may be functionally indistinguishable from phaeochromocytomas. Finally, where there is a family history the tendency to multicentricity is much higher[11].

Patients and methods

Between 1975 and 1987, 25 patients, median age 47 years (range 17-61 years), were referred to one surgeon (A.O.M.) (*Table 1*). Sixteen were women and nine were men. Twenty patients had single carotid body tumours and two patients had bilateral carotid body tumours. In two patients the tumour was associated with functioning middle mediastinal paragangliomas and one further patient had a carotid body tumour with bilateral adrenal phaeochromocytomas and a para-aortic phaeochromocytoma. Three others had vagal paragangliomas.

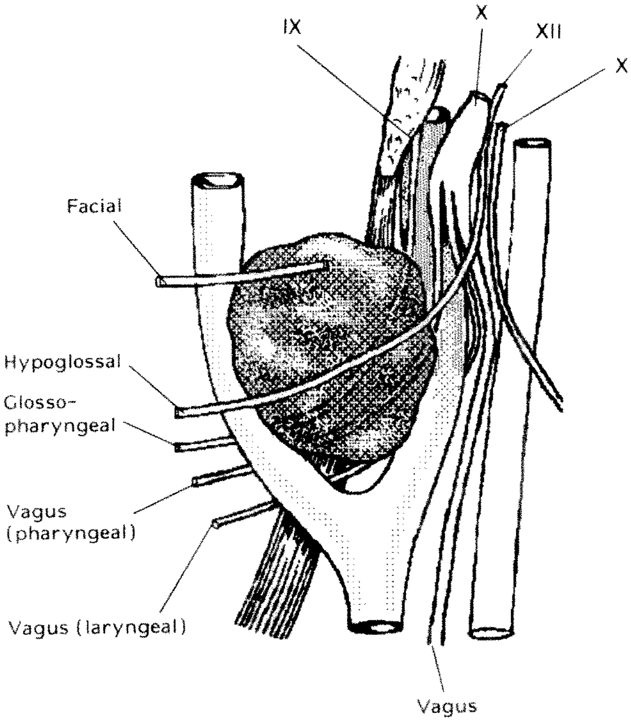

Figure 2 *Distribution of cranial nerves in relation to carotid body tumour emphasizing that the cranial nerves are at greatest risk during dissection of the upper pole and the back of the tumour*

Operative technique

Before surgery, patients are fully informed of the risks of hemiplegia and nerve damage. Patients are specifically asked for any history of dysphagia, hoarseness, difficult mastication and choking. Vocal cord movement is checked by indirect laryngoscopy. The operative approach is similar for all patients. A nasal endotracheal tube is inserted to facilitate access to the top of the tumour by having the mouth completely closed. With the patient supine and slightly flexed and the head rotated to the other side an incision is made along the length of the anterior border of the sternomastoid. Bipolar cautery is used to reduce the risk of nerve damage. Before attempting to remove the tumour it is essential to gain early control of the carotid arteries proximal and distal to the tumour using slings. It is important to identify the vagus and hypoglossal nerves as these may be adherent or even invaded by tumour. It is then possible to identify a cleavage plane between the carotid artery and the tumour within the adventitia, known as the 'White Line of Gordon Taylor'[9]. We advise starting the dissection at the bifurcation of the carotid artery and then proceeding towards the difficult area at the upper end of the tumour where there are a number of cranial nerves to be found (*Figure 2*). This plane is not always present and if there is invasion of the internal carotid artery or the common carotid artery it is necessary to insert a carotid artery shunt, resect carotid artery with the tumour and reconstruct the artery with an interposition vein graft. Usually, however, it is possible to peel the tumour off the internal carotid artery. This is a highly vascular tumour and the blood loss may be considerable. For the tumour that extends towards the base of the skull it may be necessary to mobilize the parotid gland, divide the digastric and stylohyoid muscles and the styloid process[12,13]. At the end of the operation a suction drain should be inserted and the wound closed in layers with catgut and Prolene® (Ethicon Ltd., UK).

Results

The results are given in detail in *Table 2*.

All patients presented with a lump in the neck of some duration, median 3 years (range from 2 months to 30 years). Two patients presented with cranial nerve palsies of the IX, X and XIIth nerves and two patients had hoarseness due to recurrent laryngeal nerve palsies. In three there was hypertension associated with raised vanillyl mandelic acid levels in the urine. In all but one patient who underwent a difficult biopsy before referral, the diagnosis was confirmed on angiography which showed a characteristic tumour blush in the carotid bifurcation. This procedure was not without risk: two patients had suffered a hemiparesis following carotid stab angiography before referral. It is our current practice to perform angiography using intravenous digital subtraction angiography (DSA) and this procedure was performed satisfactorily in four patients without complication (*Figure 3*). The most striking aspect of presentation was that in eight patients operative removal was attempted before diagnosis: two patients underwent an unnecessary and hazardous parotidectomy, and five had biopsy or attempted biopsy of a putative 'node'. DSA is a simple and safe investigation which will give accurate information, preventing unplanned and dangerous operations. Duplex Doppler imaging was used to diagnose a carotid tumour in one patient in this series, correctly identifying the site of the tumour between the carotid arteries and also the vascular nature of the tumour.

Using selective venous sampling of functionally active tumours two patients were found to have mediastinal paragangliomas, one at the hilum of the left lung and the other within the pericardium. Both were successfully removed. One further patient aged 17 years had had bilateral adrenal phaeochromocytoma and a para-aortic phaeochromocytoma resected before referral for removal of her carotid body tumour. Of the 25 patients, 22 underwent successful resection of carotid body tumours and a further three had excision of vagal paraganglioma. Three patients did not undergo operation as the first line of treatment but received radiotherapy. The tumours shrank

Associated functioning paragangliomas	5 (3 patients)
Local invasion of neighbouring tissues	7
Lymph node involvement	2
Follow-up period	
Median	3 years
Range	1 month–13 years
Recurrence	1

* Four patients had preoperative cranial nerve palsy and in seven the nerve was involved by malignant tumour

initially and then enlarged. In two of these it was possible to resect the tumour but in the third patient CT scanning showed intracranial extension.

Two days before resection two patients underwent embolization of their carotid body tumour using selective embolization of branches of the external carotid artery. These tumours had been previously explored elsewhere. It was difficult at definitive operation to assess whether embolization had reduced the vascularization of the tumour. Indeed in both tumours part of the blood supply arose from the internal carotid artery.

Of the 26 paragangliomas which were resected two required insertion of shunts. In both these patients resection of the internal carotid artery with replacement by an interposition saphenous vein graft was necessary. In one of these patients tumour was identified in the lumen of the artery.

Postoperative hemiplegia did not occur but there was transient cranial nerve weakness in two patients. In seven patients there was local invasion of the nerve by the paraganglioma, and the involved portion was resected with the tumour. Four of these (16 per cent) had obvious cranial nerve palsy before operation and a further three had vagal paragangliomas. The eighth patient had a large tumour and had undergone a previous attempt at removal. This was the only patient with cranial nerve damage attributable to operation (4 per cent). Histological proof of invasion of local structures, including nerve, artery and sternomastoid muscle, was obtained in these seven patients. Lymph node involvement occurred in only two patients out of 11 who had lymph nodes included in the specimen.

During the postoperative follow-up period (up to 13 years) only one patient undergoing resection has developed recurrent tumour. This patient died of neck and chest secondaries 3 years after resection.

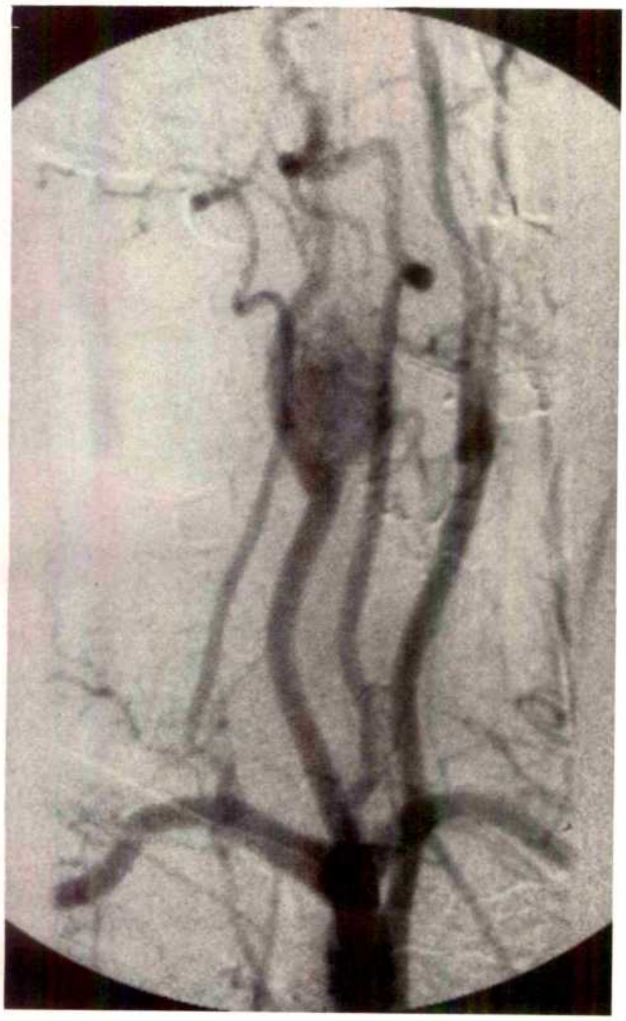

Figure 3 *Intravenous digital subtraction angiogram showing carotid body tumour at the bifurcation of the right carotid artery*

Discussion

This series illustrates several important points. First, at presentation the tumours may be multiple and associated with secreting paragangliomas elsewhere in the body. Secondly, it is now possible to diagnose carotid body tumours without angiography, and the diagnosis should now be made using the safer investigations of intravenous DSA, technetium scanning or duplex Doppler imaging. These are not hazardous and are much preferred to unplanned surgical exploration. Duplex scanning and technetium isotope scanning are entirely non-invasive methods and are suitable for establishing the diagnosis. DSA will provide an accurate plan of the tumour blood supply which is available for reference in the operating theatre. If the diagnosis is not suspected until operation the tumour must not be biopsied as this carries a high risk of stroke. The best policy is to close the wound and replan the procedure electively. If the upper limit of the tumour cannot easily be felt a computerized tomography (CT) scan should be performed to assess intracranial extension. Indeed, perhaps the most useful classification of carotid body tumours is into those with and those without previous surgery and those with and those without intracranial extension.

Preoperatively, two patients in this series had hoarseness and a lump in the neck and two others had definite cranial nerve palsies. In such patients a combined approach is necessary and should include ENT assessment of the pharynx, larynx and lower cranial nerves as well as angiographic assessment of the extent of vascular involvement. At operation, particularly for large tumours, a dual approach by vascular and ENT surgeons is recommended.

The major series of carotid body tumours reported in the last 20 years are listed in *Table 3*. Resection of carotid body tumours is associated with a mortality rate of up to 10 per cent[8], a hemiplegia rate of up to 20 per cent[8] and a cranial nerve damage rate of around 50 per cent in some series[15]. This series has a zero

Table 3 *Cervical paraganglioma: outcome of major recent series*

Centre	Year	No. resected	Mortality	Hemiplegia	Cranial nerve palsy	
					No. of patients	%
Westminster[14]	1965	8	1	1		
Mayo[8]	1971	58	4	5	14	24
Houston[15]	1972	18	0		10	56
Cleveland[16]	1978	31	1		17	55
Toronto[17]	1981	23	1		8	35
San Francisco[18]	1982	15	0		7	47
Johannesburg[19]	1986	46	2	1	8	17

St. Mary's/Hammersmith (present study)	1988	26	0	0	8	31

mortality and a zero hemiplegia rate. Cranial nerve involvement was found in 31 per cent of tumours resected. Only one patient (4 per cent) had damage to a normal cranial nerve despite a high resection rate of 96 per cent and he had had a previous attempt at removal. This series compares well with a recent report from the Mayo Clinic[20] of 153 carotid body tumours collected over 50 years. While their mortality and stroke rates have fallen the postoperative cranial nerve dysfunction rate remains unchanged at 40 per cent[20], and tends to be higher with larger tumours. Mayo Clinic workers found that the principal area of damage was in dissection of the upper end of the tumour and this is partly due to direct tumour invasion. It is possible that earlier resection may reduce the risk of cranial nerve involvement.

The technical aspects of resection have already been outlined but some points require emphasis. First, preoperative assessment should include careful pharyngoscopy as the tumour may extend into the pharynx or larynx. At least 6 units of blood should be cross-matched for the operation. At operation early control of the carotid vessels must be obtained with sacrifice of the external carotid artery if necessary. The tumour will often push the external carotid artery anteriorly. There is now no place for carotid artery ligation although division of the external carotid artery is often a useful manoeuvre to mobilize the tumour. The indication for insertion of a shunt is full-thickness invasion of the carotid artery by tumour or inadvertent damage to the carotid artery during dissection. The surgeon must be competent at insertion of carotid shunts and interposition vein grafting and thus ideally should be a vascular surgeon experienced in carotid artery surgery. Routine shunting is not necessary but a shunt should be readily available for every operation. Resection with complete rather than partial excision should be the aim of every operation. For patients with bilateral tumours the approach should be staged into two operations because of the risk of bilateral vocal cord palsy and between the two operations the vocal cords should be checked.

Postoperatively the patient should be managed in a high dependency unit in the prone position with monitoring of the blood pressure and neurological status. The patient should not drink any fluids until fully conscious. A doctor must be in attendance at the first drink as the patient may aspirate in the presence of cranial nerve damage.

The experience of this series suggests that while the tumour is often locally malignant (30 per cent of patients) lymph node involvement only occurred in 8 per cent of patients. This is in contrast to the South African series from Witz University where there was a 20 per cent incidence of lymph node involvement[19]. It is likely that metastasis is a late event. Martin *et al.* (1973)[7] reported on the natural history of 28 patients with carotid body tumours who received no treatment. Observed over a mean period of 11 years, seven developed node metastases and two died of distant metastases.

There are only two other treatment options: embolization and radiotherapy. Radiotherapy has been reported to have a high success rate with disappearance of the tumour in nine of 12 patients[21]. However, in three of our patients these tumours recurred after a short period of time, presenting a formidable operative risk; two were resectable, one had intracranial tumour extension and no treatment was possible. Embolization has been reported as a useful preoperative manoeuvre[22] and was used in two of our patients but did not significantly reduce the operative bleeding as the tumour received a blood supply from the internal carotid artery. It also carries a risk of hemiplegia and we have now abandoned this procedure except for large technically difficult tumours where there has been previous surgery. As palliative treatment of an unresectable tumour, embolization may have a useful role.

In conclusion, carotid body tumours form only part of a complex pattern of paragangliomas, some of which may secrete catecholamines[23]. These tumours may be diagnosed by the relatively safe method of intravenous DSA and duplex Doppler scanning. As these tumours are locally malignant, resection offers a chance of cure particularly if performed when the tumour is small. However, resection may require the insertion of a carotid shunt during the operation and for large or complicated tumours a combined team of ENT and vascular surgeons is preferable. Following successful resection the outlook is good and tumour recurrence is uncommon.

Viscoelastic properties and collagen content of the long saphenous vein in normal and varicose veins

Veins taken from patients undergoing surgery for varicose veins were compared with those obtained from patients undergoing other surgical procedures ('normals'). Varicose veins had a lower breaking strength and breaking energy than normal veins. Elastic stiffness was less in normals ($\tan\theta = 41$ (24)) than in varicose veins ($\tan\theta = 55$ (18); $P<0{\cdot}01$). There was no difference in viscoelastic behaviour between samples taken above, at, or below the valve leaflet insertion. In normals, perivalvular vein wall exhibited a 50 per cent lower breaking strength and elastic stiffness than vein from other sites. Collagen content was significantly higher in normal vein specimens in all sites examined (mean collagen content = 70 (21) μg/mg, versus *51 (20) μg/mg for varicose veins; $P<0{\cdot}001$). We conclude that significant structural changes are seen in varicose veins. In normal veins, the perivalvular vein wall has distinct viscoelastic features when compared with vein wall from other sites. This difference was not found in veins which became varicose.*

Keywords: Varicose veins, long saphenous vein, viscoelasticity, collagen, venous valves

It has long been recognized that valvular incompetence is invariably present in patients with varicose veins. This defect permits reverse flow in the diseased veins and an abnormal outward and retrograde flow of blood from the deep system to the superficial veins following muscular exertion. In 1603 the anatomist Heironymous Fabricius of Aquapendendente wrote that valves were created by nature to ensure a 'fair general distribution of the blood'[1]. The special role of valves in counteracting the consequences of muscular activity on venous return, rather than acting as antigravity devices, is now universally acknowledged.

In this study we have analysed the viscoelastic properties and collagen content of varicose and normal veins. We have tried to identify a locus in the vein wall adjacent to the venous valves which could become dilated or varicose and render the vein incompetent.

Materials and methods

Fresh samples of the long saphenous vein were obtained from patients undergoing surgery for extensive thigh block dissection (usually melanoma) or from graft procedures or amputated limbs. Varicose veins were taken from vein stripping procedures using a Babcock stripper. The entire vein was dissected open, longitudinally pinned out and measured, and the number of valves counted. Using a preset cutter, 3-mm samples were cut circumferentially from segments of the long saphenous vein, at the thigh, near the knee and near the ankle. Vein wall sections immediately adjacent to the valve leaflet insertion ('perivalvular vein wall') were studied in greater detail, and 3-mm samples taken from just 'above', 'at' and immediately 'below' the valve leaflet site. Samples above and below the valve were carefully taken to exclude any valve tissue. Significant variceal dilatations or sacculations, when present, were also sampled and analysed separately.

Viscoelastic studies

The excised samples were first mounted in an extensiometer (constructed in the Department of Surgery, University of Wales College of Medicine) which features two serrated-toothed clamps set 3 mm apart at zero tension. The tissue was kept moist at all times in cool Ringer's solution buffered to pH 7·4 and sandwiched with a piece of filter paper between the jaws of the two clamps, to avoid crushing and disruption at the attachment points. The specimen was disrupted by the progressive separation of the jaws, driven at 3·1 mm/min, and thereby subjected to a constant deformation rate. The load-deformation viscoelastic curve was processed by strain gauge force transducers connected to a Wheatstone bridge. The output was displayed on a chart recorder (chart speed: 31 mm/min) via an instrumentation amplifier. From the several measurements provided by the deformation curve (*Figure 1*), three were examined in detail[2]:

Breaking strength. F_{max} is the force or load required to disrupt the vein wall, expressed as the load in grams per unit cross-sectional area in millimetres squared (g/mm^2).

Breaking energy. The total energy required to disrupt the specimen obtained from the area of the viscoelastic curve up to breaking point,

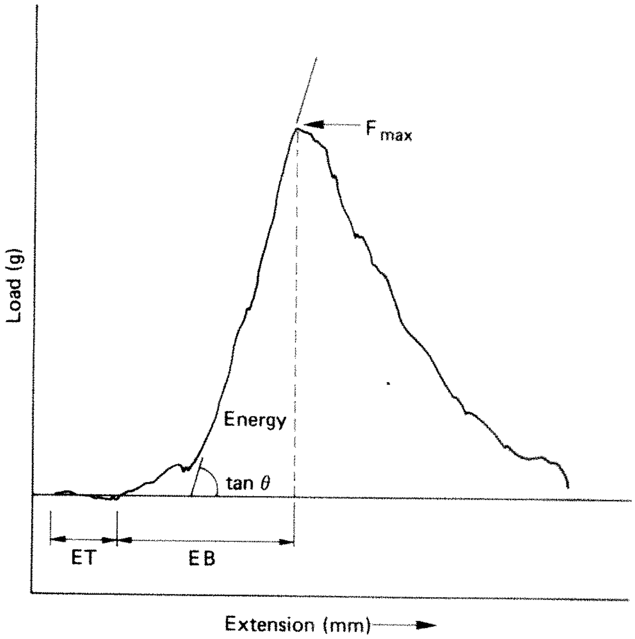

Figure 1 *A typical viscoelastic curve for (varicose) vein wall. ET, extension to take-off; EB, extension to breakage; F_{max}, load required to achieve breakage or breaking strength; energy, total energy required to break the specimen (area of curve to breaking point); tan θ, elastic stiffness*

Table 1 *Viscoelastic properties of varicose and normal veins*

	Normals	Varicose veins
Wall thickness (mm)	1·18 (0·4) $n = 50$	1·48 (0·4) $n = 27$
Breaking strength (F_{max}, g/mm^2)	97 (100)† $n = 50$	49 (28) $n = 26$
Breaking energy (mm^2/mm^3)	47 (59)† $n = 50$	19 (7) $n = 27$
Elastic stiffness (tan θ)	41 (24) $n = 50$	55 (18)* $n = 27$

Values are means with s.d. in parentheses; * $P < 0·01$; † $P < 0·005$ (normals *versus* varicose veins)

Table 2 *Viscoelastic characteristics of the long saphenous vein according to anatomical site*

	Breaking strength (g/mm^2)	Breaking energy (mm^2/mm^3)	Elastic stiffness (tan θ)
Thigh	110 (71) $n = 42$	76 (45) $n = 44$	59 (21) $n = 39$
Knee	74 (48) $n = 19$	24 (14)* $n = 17$	60 (20) $n = 18$
Ankle	50 (30)† $n = 16$	14 (5)† $n = 15$	58 (17) $n = 17$

Values are mean with s.d. in parentheses; † $P < 0·001$ (thigh *versus* ankle); * $P < 0·01$ (thigh *versus* knee)

and expressed as area in millimetres squared per unit of tissue volume in millimetres cubed (mm^2/mm^3).

Elastic stiffness. The deformation rate was obtained from the linear part of the curve and measured in degrees as the tangent of the angle α (tan θ).

The thickness of the vein sample was measured at room temperature by means of an optical micrometer, while assembled in the tensiometer jaws at zero tension.

Collagen estimation. The vein samples used for tensiometry were weighed and kept frozen at −70°C. Previous work has shown that collagen content did not change in samples stored for up to 3 weeks. Hydroxyprolene content was determined by Woessner's assay[3], this amino acid being almost exclusively present in collagen. Hydroxyprolene content was expressed as micrograms per milligram of wet weight of tissue.

Statistics

All values were fed into a computer file (Honeywell DPS-8/70 Waltham, Massachusetts, USA) and analysed by a Minitab package (release 513). Data values were read in columns and the variables extensively plotted (scattergrams) for any positive correlation or significant sex or age differences. Histograms were constructed to ascertain data distribution, skewness, and kurtosis. Statistical significance was tested by the two-sample Student's t test, and P values $< 0·05$ were taken as indicating significant differences. All results are expressed as the mean and standard deviation (s.d.). Data which were not normally distributed were analysed by the Mann–Whitney U test.

Results

The results of a typical strain-deformation curve are shown in *Figure 1*. In the slow initial extension phase the vein exhibited plastic behaviour and the curve was relatively linear, facilitating calculation of the slope angle or elastic stiffness (tan θ).

Macroscopic features

An average of 3·6 (1·9) valves were found in the long saphenous vein sample taken from patients with varicose veins, with a higher proportion of valves found in the proximal (thigh) vein (average 2·0 (1·4), $n = 36$) than distally in vein from the knee or leg (average 0·8 (0·7), $n = 26$ and 0·7 (0·6), $n = 21$ respectively). Patients with normal veins showed no significant difference in overall valve frequency, with an average of one valve every 11·4 cm, compared with every 12·8 cm in varicose vein patients.

Average vein wall thickness was slightly greater at the knee (1·61 (0·6) mm) than at the thigh (1·37 (0·5) mm) or ankle (1·39 (0·5) mm, $n = 14$), both in normals and patients with varicose veins.

Sacculations or local dilatations ('blow outs') of the vein wall were infrequently seen, being present in only 33 per cent of veins. These were closely associated with valve cusps, but not sited preferentially above or below the valve leaflets, being found more frequently in the thigh (average 0·5, $n = 32$) than in knee (average 0·3, $n = 26$) or leg (average 0·15, $n = 26$) samples of vein.

Viscoelastic behaviour

Breaking strength and breaking energy were significantly greater in normal veins but varicose veins showed a higher elastic stiffness (*Table 1*).

In both normal and varicose vein patients, vein taken from the ankle had a significantly lower breaking strength than thigh or knee vein (*Table 2*). Similarly, breaking energy was found to be highest at the thigh and least at the ankle. Elastic stiffness did not alter significantly for any of the three sites examined.

Vein wall characteristics adjacent to the valves

At the three sites immediately adjacent to the valve cusps, i.e. just above, at and below the valve leaflet, there was no difference in vein wall thickness, breaking strength, breaking energy or elastic stiffness (*Figure 2*). This finding was confirmed both in normal veins and in samples taken from patients with varicose veins.

On comparing vein wall samples taken adjacent to the valve leaflet site with those obtained from other parts of the vein, no significant difference in viscoelastic behaviour was found in patients with varicose veins. In normals, however, there was a significant difference in breaking strength, with a 50 per cent reduction in tensile parameters at the perivalvular vein wall. Similarly, elastic stiffness was markedly lower in vein wall adjacent to the valve leaflet than at other sites (*Table 3*).

Collagen content

Samples of vein taken from patients with varicose veins yielded a lower average hydroxyprolene content than those taken from normal patients (normals, 70 (21) μg/ml wet weight, $n = 43$ and varicose veins, 51 (20) μg/mg, $n = 42$; $P < 0·001$). The difference between these two groups was observed in all sites examined, including samples taken above, at or below the valve cusps (*Figure 3*).

Discussion

Brodie[1] in 1900 defined a 'varicose' vein (from Latin *varus* for 'bent or crooked'[4]) as one which is 'unnaturally dilated'. Many authors have since observed that varicosities tend to develop within the tributaries or stem branches of the long saphenous vein[5,6] and are often limited to the thigh[7] or found only below the knee[6]. In his thesis, Cotton[6] summarized three distinct features of varicose veins: (1) a localized dilatation or sacculation (termed a 'varix') found below the valve leaflet; (2) a simple cylindrical dilatation of the vein or 'aneurysm' formation; (3) a serpentine or 'spiral' elongation of the smaller tributaries. Histological examination of the vein reveals, even at an early stage, widespread muscle hypertrophy and disruption of the elastic lamina[6]. Fibrosis and other focal changes are subsequently seen within the muscle cells, but these are not uniformly found throughout the vein wall[6–10]. The elastic lamina may degenerate and become indistinct. Recent studies of the vein wall using light and electron microscopy reveal an abnormality of the muscle cell associated with collagen infiltration[10].

We frequently observed dilatation of the saphenous vein but were unable to quantify this in excised specimens. The commonest and most striking change of discrete unilateral sacculations[11] was randomly found at the level of the valve cusps, but always closely associated with the leaflet insertion site. Our stress studies comparing three sites, above, at, or below the valve cusps, failed to identify a specific portion of the vein wall which was prone to develop structural weakness, both in normals and in patients with established varicose veins (any sacculations we tested were structurally weaker and less elastic than normal vein wall). The vein wall surrounding these localized dilatations is reported to show intact tissue layers on histological examination[6].

In varicose veins the vein wall becomes attenuated at the valve sinus, with effacement of the 'commissural mound' in between the valve cusps (the 'agger'), presuming a pre-existing locus of wall weakness[10]. A pre-existing structural defect close to the valve leaflet has not been previously identified[12,13], and is confirmed in our studies on normal vein. The difference in structural behaviour between perivalvular vein wall and other parts of the vein wall was not present in established varicose veins, reflecting the pathological changes within the tissue layers[6,9]. In a similar study comparing the tensile strength of the actual valve leaflet with valve wall within the femoral vein, the valve cusps were found to be slightly stronger than adjacent vein wall[13].

There is wide variation in the reported number of valves present in the long saphenous vein, ranging from zero to 20[5,6,13–19]. Few authors have compared normal with varicose veins, with no published phlebographic studies documenting the number of functional valves[19], although it has recently been suggested that the sinusoidal 'bulges' seen radiologically correlate poorly with the presence of valves[16]. We were impressed by the low incidence of venous valves within the long saphenous trunk, both in normals and in varicose vein patients.

The collagen content of vein samples taken from normal patients was higher, in our study, than for varicose vein patients. This difference is unlikely to be a localized or chance finding, as it was consistently found at all three sites examined adjacent to the valve insertion, and has been confirmed by other authors[20]. It may reflect the morphological changes seen in varicose veins, which are known to contain a higher proportion of muscle cells[6,10] and show fatty infiltration in the vein wall[21].

It has been argued that a generalized distensibility of the vein wall results in secondary incompetence of the valve cusps[22]. Various valve defects have been reported, including congenital valve absence[23], an evagination or herniation at the commissures[11], adhesions, bulging and endothelial irregularities which may inhibit valve function[17], and a 'valvulitis'[24]. Architectural valve changes have been observed in animal models subject to venous hypertension[25]. Arteriovenous fistulae may play a role in the formation of varicose veins[26]. From our studies, it appears that changes in perivalvular vein wall structural behaviour are accompanied by an overall reduction in collagen content. These may result from an enzyme defect affecting the biosynthesis of a genetic collagen type (as postulated for arterial aneurysm formation[27,28]). Indeed, as also reported by others[29], we have observed varicose vein formation in a patient with localized Ehlers–Danlos syndrome below the knee (unpublished findings). The functional significance of the diverse collagen types found in vascular tissue is not fully understood[28], and may yet prove to be relevant in understanding the causation of varicose veins.

Mr D. C. Berridge

Twelve patients with a clinical diagnosis of possible vascular graft infection have been studied over the last 3 years. All patients had their leucocytes labelled with indium-111 and γ-camera imaging after 24 and 48 h. Subsequent management was according to established surgical techniques. Eight patients proved to have vascular graft infection and indium uptake was seen along the length of the graft in six. Two patients with open wound infections and synthetic grafts had localized uptake only on leucocyte scanning. Four patients, all of whom had negative scans were not thought to have infected grafts after further investigation using digital subtraction angiography and computed tomography scanning. These patients have been followed up for a median period of 19 months (range 5–25 months) and have remained symptom free. Initial experience with ^{111}In-labelled leucocyte scanning has been encouraging, both in diagnosis and in planning the management of patients with graft infections.

Keywords: ^{111}In-labelled leucocytes, vascular graft infection

Vascular surgery has always been regarded as being relatively 'clean' surgery, especially in the elective or non-trauma patient. However, infection of a prosthetic graft occurs in up to 6 per cent of patients undergoing vascular reconstruction, and is associated with high mortality and morbidity rates[1–3]. In the early stages it can be difficult to distinguish between a superficial wound infection and a localized graft infection. Various modalities[4–6] have been used to attempt to improve the diagnosis of graft infection with the hope that earlier diagnosis will allow early aggressive local treatment.

Therefore, we have undertaken an evaluation of ^{111}In-labelled leucocyte imaging in patients with a clinical diagnosis of possible vascular graft infection. The management of these patients was not altered by the result of the radionuclide scan to allow the eventual clinical outcome to be correlated with the radionuclide scan findings.

Patients and methods

Patients

Over the last 3 years (1985–1987), 12 patients with a clinical diagnosis of possible graft infection have been evaluated with ^{111}In-labelled leucocyte scintigraphy. They were predominantly male patients (11:1) with a mean age of 62·4 ± 8·7 years. Indicators of possible graft infection included persistent pyrexia or leucocytosis, persistent wound discharge with positive culture, infected false aneurysms, graft tenderness, and/or general malaise or abdominal pain in the absence of other identifiable pathology.

Methods

Labelling of leucocytes with ^{111}In-oxine

A sample of 17·5 ml of the patient's blood was placed in a plastic tube (20 ml) (Sterilin Ltd., Feltham, UK) containing 3·5 ml of acid/citrate/dextrose (ACD) solution and gently mixed. This tube was then incubated at 37°C for approximately 45 min to sediment the erythrocytes.

Using a slightly modified method of Peters *et al.*[7], a mixed leucocyte ^{111}In-oxine labelling was performed in saline/ACD, but the period out of contact with plasma was kept as short as possible. Five millilitres of the cell-free plasma was added, mixed by gentle inversion and then centrifuged at 900 r.p.m. for 10 min. The supernatant was then discarded.

The leucocyte pellet obtained was resuspended in a further 5 ml of cell-free plasma and the preparation was finally assayed for activity.

Cell-free plasma was obtained by centrifuging the platelet rich plasma at 2400 r.p.m. for 10 min. The supernatant cell-free plasma was removed and stored at 37°C until required.

Actual activity injected was approximately 10 – 11 MBq.

Imaging was performed at 24 h and 48 h on an IGE 400T γ-camera fitted with a medium energy collimator and using both peaks of indium-111.

Results

There were no complications associated with the technique in any of the patients studied. The median period to presentation was 10 weeks (range, from 2 weeks to 4 years). Of the 12 patients studied, there were four negative scans, two with only localized uptake and six with either multifocal or full-length uptake.

Negative ^{111}In-labelled leucocyte images (Table 1)

The usual presenting feature was a pyrexia associated with abdominal pain and general malaise. Spontaneous improvement was seen in three patients and a urinary tract infection was confirmed on subsequent culture in the fourth patient. In one patient a resolving non-infected haematoma was monitored with serial computed tomography (CAT) scans.

Positive ^{111}In-labelled images

Localized uptake (Table 1). Both patients had a persistent groin discharge with culture of *Staphylococcus aureus*. Appropriate intensive intravenous, local gentamicin beads and subsequent oral antibiotic therapy cleared the infection in the latter patient, with a patent graft remaining at 14 months. The other patient failed to respond and required graft excision and a subsequent Gritti–Stokes amputation. At operation (a month after imaging) the entire length of the graft had become infected—he died after a stroke 8 months later.

Full-length or multifocal uptake (Table 2). All six patients had highly positive images (*Figure 1*) and positive cultures from either a discharging wound or sinus. *Staphylococcus aureus* was found in all cultures, and *Streptococcus* sp. was also found in one case. Five (83 per cent) had had multiple vascular procedures performed over a period of up to 7 years. Two patients required a below-knee amputation following occlusion of the graft and

before any recognition of graft infection. All patients failed to respond to intensive antibiotic therapy in association with graft drainage. Subsequent to graft excision, amputation was necessary in a further three patients (50 per cent). An asymptomatic metastatic chest wall abscess was detected in one patient and was subsequently drained (*Figure 2*). Differential uptake clearly separated an infected femoropopliteal (polytetrafluoroethylene) graft, from an uninfected axillofemoral (Dacron®, E. I. Dupont de Nemour Inc.) graft in the same patient (*Figure 3*). There was no operative mortality; however, two patients died, one from a ruptured aortic aneurysm, and one from a stroke 8 months later. All wounds have healed in the survivors.

Median follow-up time for patients with negative or localized positive scans is now 19 months (range, 5–25 months).

Discussion

Most of the patients with positive images had undergone multiple vascular procedures over a variable period of time up to 7 years. It is therefore difficult to be certain when the infection commenced, as it is known that prosthetic grafts can become infected many years after the initial operation[8,9].

Although infections in the six patients with full-length or multifocal images were suspected clinically, the images obtained were distinct. Similarly, the four patients with negative scans have all failed to demonstrate any sign of graft sepsis on subsequent follow-up. It is, however, more difficult to be certain of the interpretation of a localized positive image. Serial imaging after antibiotic therapy and any necessary drainage procedure may help in these particular cases. The main advantage of this technique is in the detection of localized infection which may allow early localized treatment with reduction in morbidity and mortality.

False positives may occur; one reason is that platelet contamination inevitably occurs as a result of this mixed leucocyte labelling technique, although this was not the case in the present study. False positive images may be accounted for by uptake in accessory spleens, bowel, bladder, lung in cystic fibrosis[10], and also in both primary and secondary neoplasms[11]. False aneurysms have also been reported to cause false positives[12]. Thus the interpretation of these scans should be based on the clinical status of the patient and knowledge of the site of the grafts. Any unexplained positive images should be fully investigated using alternative techniques.

Other methods which have been used have disadvantages. Ultrasound and computed axial tomography scans may show a perigraft collection of fluid; this does not necessarily confirm infection. The presence of air bubbles in the perigraft fluid allows a more confident diagnosis on CAT scanning[4,13]. However, most common pathogens found in infected grafts are *S. aureus* and *Escherichia coli*., which do not produce gas[14]. Aspiration of perigraft fluid under ultrasound or CAT control can allow both confirmation of infection and determination of sensitivity[15], but is also subject to sampling error and has the increased risk of fatal haemorrhage in the presence of infection.

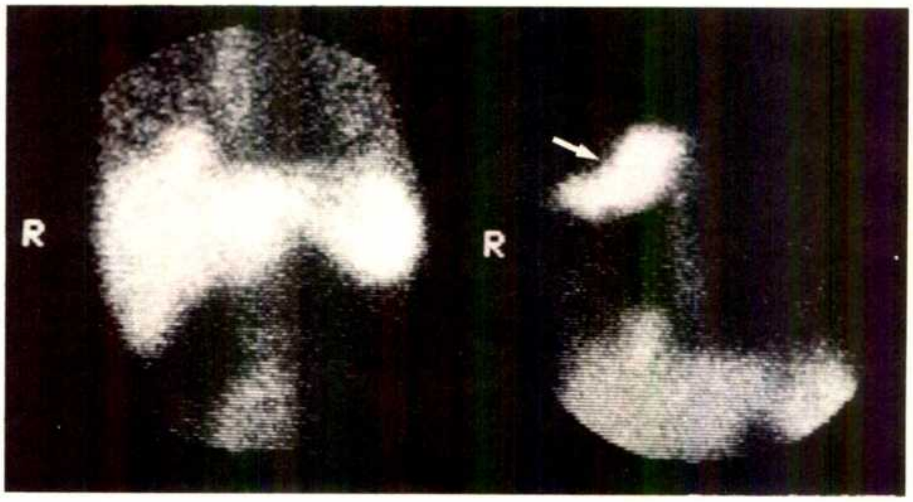

Figure 2 ^{111}*In-labelled leucocyte scan showing an occult chest wall metastatic wall abscess (arrowed)*

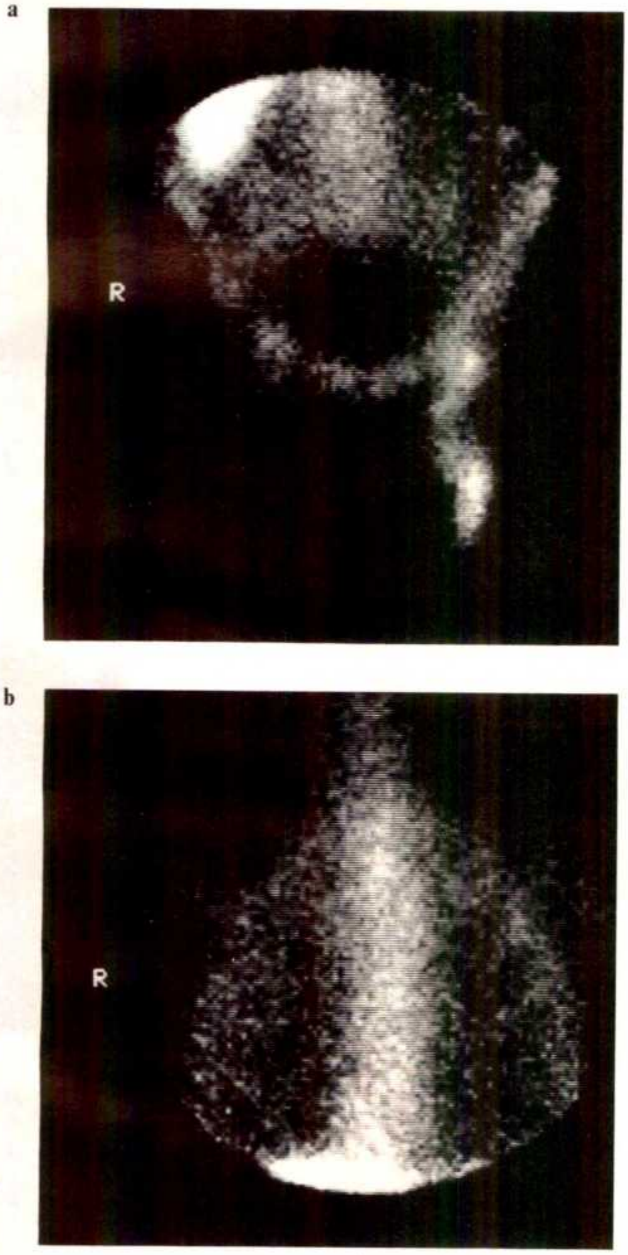

Figure 3 ^{111}*In-labelled leucocyte scan showing:* **a**, *multifocal and full-length uptake in a left femoropopliteal graft (polytetrafluoroethylene);* **b**, *(the same patient as* **a***) a left axillofemoral graft with no increased uptake*

Furthermore they do not reveal the extent of the infection. An opposite conclusion was reached by Mark *et al.*[13]; however, this was based on three cases where ^{111}In-labelled leucocytes had demonstrated groin infection but had not shown retroperitoneal infection. The CAT scan was considered positive after revealing perigraft fluid, but this is not specific to infection alone.

^{111}In-labelled leucocytes are preferred to gallium citrate, because the latter has a lower sensitivity and has a longer delay before imaging is possible[16]. Williamson *et al.*[17], using autologous ^{11}In-oxine-labelled leucocytes, found a sensitivity of 100 per cent, a specificity of 88 per cent, and an accuracy of 93 per cent. All scan positive patients were explored and infection confirmed. They also found that CAT scan evaluation was inferior; if fluid or gas was needed to identify graft infection then the sensitivity would be only 37 per cent. Similarly, antibiotic therapy[18] or the chronicity of infection[19] does not impair the sensitivity. Newer radiopharmaceuticals such as technetium-99m hexametazine (HM-PAO, Ceretec, Amersham International, Amersham, UK) appear promising and may allow quicker, higher definition images which may be of particular use in the aortic region. An additional advantage of ^{111}In-labelled leucocyte imaging, is that other sites of infection may also be revealed which might otherwise adversely affect the prognosis of that patient.

Radionuclide imaging of patients with grafts appears to offer a superior method of diagnosing graft sepsis but remains underused[20]. Patients with true positive scans have a significantly increased mortality[21]. The use of ^{111}In-labelled leucocytes in this study has proved helpful in clinical practice. This technique may allow detection and treatment of infection while it is still localized, and therefore may allow local treatment of infected prosthetic grafts[22] with reduction in morbidity and mortality. It has also been shown to allow the differential management of infected and uninfected grafts within the same patient.

Risk factors in onychocryptosis

A study is described in which the normal toes of 50 patients with unilateral ingrowing toenails were compared with those of 50 healthy subjects matched for age and sex. Twenty-one potential risk factors were compared between the groups. All measurements on patients were derived from unaffected toes in order to avoid anatomical distortion due to the disease process. Statistical analysis revealed significant differences between the groups for three anatomical measures, namely nail fold width ($P<0{\cdot}001$)*, medial rotation (eversion) of the great toe* ($P<0{\cdot}02$) *and nail thickness* ($P<0{\cdot}03$)*. Possible discriminating variables were assessed using linear discriminant function analysis and a mathematical equation was derived based on these three factors. This equation was found to possess a potentially high predictive value in that it correctly classified 86 per cent of the patients and 77 per cent of the controls. A further group of 62 unselected patients presenting with unilateral onychocryptosis and 35 unaffected controls were assessed for these three parameters. Of these, 80 per cent of controls and 85 per cent of patients could be classified correctly by the equation. It is thus proposed that, in the majority of subjects with onychocryptosis, a discrete anatomical predisposition exists and that the other factors act only as triggers in the development of the condition. This study provides a rationale for less traumatic surgical approaches to ingrown nail than nail avulsion, with or without nail bed ablation and may also provide a means of identifying high-risk groups.*

Onychocryptosis, frequently termed 'ingrown nail' has been attributed to a multiplicity of factors including faulty nail-trimming[1-6], abnormally shaped nail plates or nail folds[6,7], excessive sweating[5], tight footwear[1,5], poor hygiene[3], excessive weight-bearing[6], inherited factors and trauma[3,8]. It is more common in males, having a 2:1 sex ratio and affecting patients most commonly between 10 and 30 years of age. It is frequently a recurring disease and numerous conservative and surgical treatments have been advocated.

Many factors cited as relevant to the development of the disease are based on opinion although three large series of patients have been studied by Fowler[5], Vandenbos and Bowers[6] and Lloyd-Davis and Brill[2]. None included comparative control subjects. The remaining literature is anecdotal and the variations in the normal population of the risk factors purported to be relevant to the development of the condition have not been defined. It is clearly essential to collect comparative data on potential risk factors in both patients and unaffected controls if there is to be any attribution of risk.

The following study was designed, therefore, to compare a number of parameters that might be relevant as risk factors in patients and age and sex-matched controls. It was conducted in two stages.

Materials and methods

Study 1

Fifty patients attending the London Foot Hospital were entered into the study. Patients were included providing that no surgical intervention had occurred and that only one foot was affected (unilateral disease). This enabled the unaffected foot to be used for comparison with control subjects in relation to anatomical parameters.

An age and sex-matched control group was obtained from employees of the Wellcome Research Laboratory (Beckenham, Kent, UK) and from pupils of the Cardinal Vaughan School (West Kensington, London, UK).

Patients and controls were assessed by questionnaire and by examination for a variety of parameters derived both from the literature and from observations by the authors (*Table 1*).

Sweat gland counts were obtained from the soles of the feet after occlusion in polythene for 5 minutes using the colloidal graphite technique described by Thomson and Sutarman[9]. This technique allows identification of both active and inactive glands.

Nail thickness was measured with Vernier callipers at the mid-point of the free edge of the nail. Medial rotation of the great toe was assessed

Table 1 *Variables used in statistical comparisons*

1. Family history of the disease	—scored present or absent
2. Body weight	
3. Shoe size	
4. Weight:shoe-size ratio	
5. Bunching of the toes	—scored present or absent
6. Mode of cutting	—convex short —convex —straight short —short
7. Sweat glands (total)	
8. Sweat glands (percentage active)	
9. Sedentary occupation	—scored present or absent
10. Nail fold width	
11. Nail thickness	
12. Divergence of nail folds	—scored present or absent
13. Medial rotation of great toe	—scored present or absent
14. Picking of the toes	—scored present or absent
15. Nail up to end of nail fold	—scored present or absent
16. Subjective opinion of sweating	—more than average —average —less than average
17. Foot hygiene	—average —less than average
18. Cross-sectional area of toe	
19. Curvature ratio of nail	
20. Lateral angle of nail	
21. Medial angle of nail

in the standing position because it tends to occur during weight-bearing. Both feet were assessed in patients and controls.

The nail fold width, the parallelism of the folds (i.e. divergence or convergence) and the cross-sectional area of the toes was assessed from a plaster replica of the toe which was obtained using dental impression material and dental plaster. The nail curvature was determined using anterior photographs of the casts. Three parameters were identified to assess the relevance of the variable curve of the nail: lateral and medial angle and a nail curvature ratio. These are represented in *Figure 1*.

Both toes were examined in all subjects and comparisons were made between the mean values for the controls and the values obtained from the unaffected toes of the patients. The measurements used for the controls were based on the mean values from both feet as there was no significant difference between left and right feet; the mean, therefore, provided the most precise measure available.

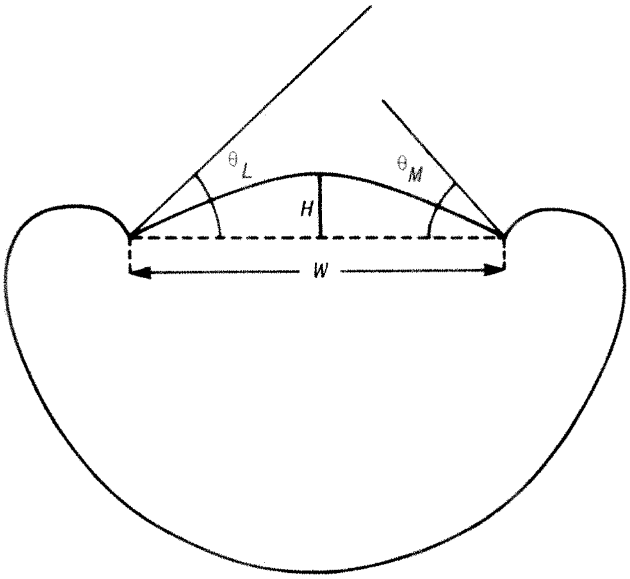

Figure 1 *Diagrammatic anterior cross-sectional view of a right toe cast showing the measurements used for nail curvature. Curvature ratio, H/W; θ_L, lateral angle; θ_M, medial angle*

Use of measurements from a single foot for patients but from the mean of both feet for controls may result in some difference in variability between the groups. It was felt that the discriminant analysis would be robust to these differences because intrapatient variability is small compared with interpatient variability.

Interdependencies of the 21 variables were tested within each group using *t* tests, χ^2 tests or Spearman's correlation as appropriate. The data were then analysed by linear discriminant analysis using stepwise multiple regression in order to identify a subset of the variables which would discriminate well between the controls and patients.

Study 2

Following the identification of such a subset of variables and the subsequent derivation of a potentially predictive equation for ingrown nail, a further patient sample was assessed for these subset variables. A total of 62 further patients attending the London Foot Hospital were examined for nail fold width, nail thickness and the presence or absence of medial rotation by a number of independent observers using Vernier callipers and assessment of rotation in the standing position; 35 controls were similarly examined. The resultant data were substituted in the equation in an attempt to substantiate the potential of such measurements as predictors of the disease.

Results

Study 1

The comparability of the patient and control groups for age and sex is shown in *Figure 2*. Features of the patient sample are shown in *Table 2* and are comparable to other patient surveys in terms of male predominance and lateral nail fold involvement.

Significant differences were found in patients between affected and unaffected toes for parameters such as nail fold width and mean cross-sectional area due to inflammatory oedema and infection. The presence of disease in one great toe did not induce medial rotation of the great toe of the other foot by causing excessive weight-bearing on the unaffected side. Medial rotation was consistently either present or absent in both great toes of all patients. No significant differences in anatomical parameters were found between right and left toes in controls, including medial rotation of the great toes. Mean values for anatomical measurements in controls were thus compared with measurements from the unaffected toes of patients.

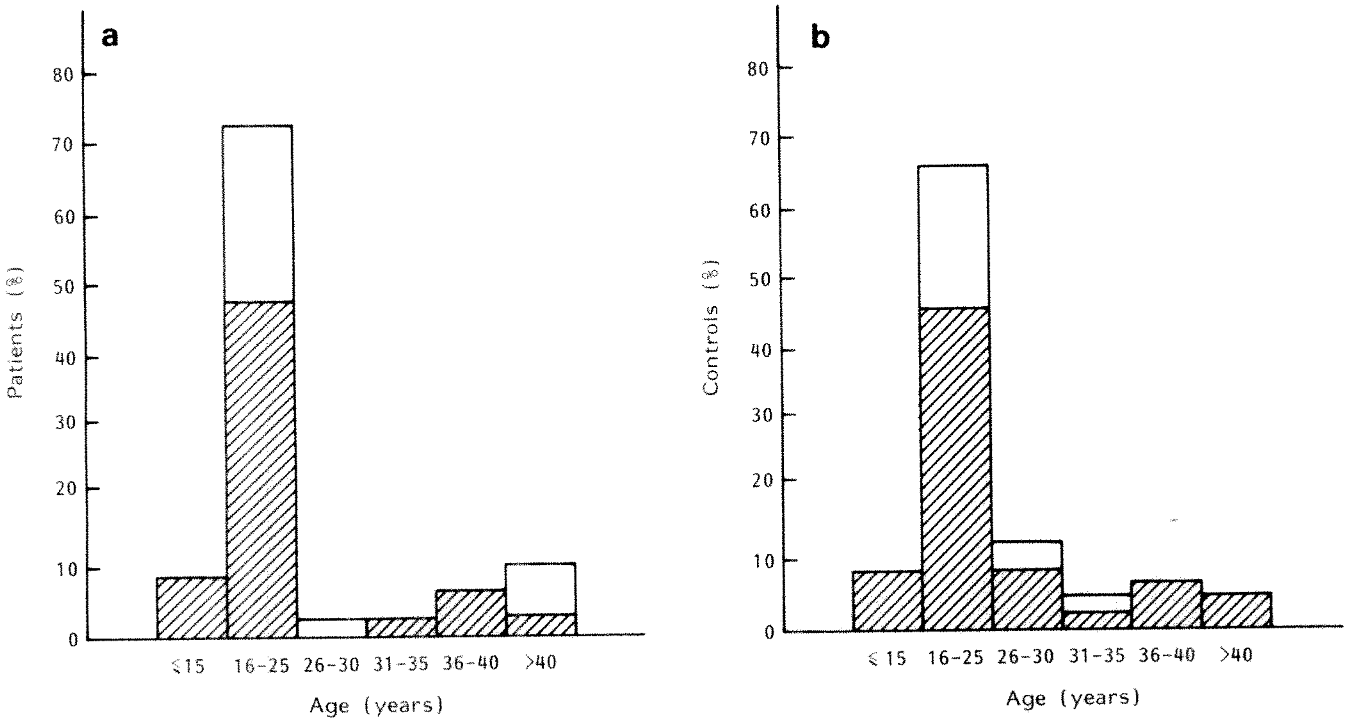

Figure 2 *Age and sex distribution of patients and control subjects. Patients: mean age 23·9 years, range 11–69 years;* □, *females* (n = *17*); ▨, *males* (n = *33*). *Controls: mean age 24 years, range 11–64 years;* □, *females* (n = *15*); ▨, *males* (n = *35*)

Twenty-one variables were available for analysis (*Table 1*).

In a comparison for each variable between the groups the only observed differences related to toe and nail anatomy and a family history of the disease. Patients tended to possess wider nail folds and thinner, flatter nails than control subjects and also more commonly volunteered a family history of the disease in first- and second-degree relatives. It was interesting that many of the factors previously proposed in the literature as being relevant to the development of ingrown nail were found to be equally common in patients and controls.

The interdependence of the variables was tested within each group using χ^2 tests, t tests or correlation depending on the types of variables. Nail curvature, nail thickness and nail fold width were found to be interdependent to varying degrees.

In order to construct the simplest possible predictive model, the data were analysed by linear discriminant analysis using stepwise multiple regression in order to identify a subset of variables which together would discriminate well between the controls and patients.

The following factors were found to be significant: (1) nail fold width (approximate P value $<0{\cdot}001$); (2) medial rotation (approximate P value 0·015); (3) nail thickness (approximate P value 0·030). The remaining variables did not approach significance once these first three had been entered.

The linear discriminant function (z) was calculated as:

$$z = x_1 - 5{\cdot}13x_2 + 67{\cdot}8x_3$$

where x_1 = nail fold width in inches × 10^{-3}
x^2 = nail thickness in inches × 10^{-3}
x_3 = 1 if medial rotation was present,
0 if medial rotation was absent
(5·13 and 67·8 are the regression coefficients)

The z value half-way between the two group means was 253 so this value was used to discriminate between potential sufferers and non-sufferers: thus if z was <253, subjects were classed as potential non-sufferers, but if z was >253, subjects were classed as potential sufferers. Using this criterion it was possible to attempt reclassification of patients and controls: the criterion classified 77 per cent of controls and 86 per cent of patients correctly.

Table 2 *Features of patient sample*

Parameters	Percentage of patients ($n=50$)
Male sex	66
Involvement of the right toe	50
Involvement of the medial fold only	14
Involvement of the lateral fold only	72
Involvement of both folds	14
Presence of pus	72
History of direct trauma	32
Presence of previous episodes	30

Table 3 *Age and sex of subject (study 2)*

	Patients	Controls
No. of subjects	62	35
Mean age (range) in years	21·9 (9–55)	21·8 (10–63)
Sex ratio (M:F)	1·9:1	1:1·5

Study 2

The age and sex of the patients and controls in the second phase of the study are shown in *Table 3*. There was an imbalance of sex ratio between the two groups studied but the age balance was comparable. In view of the male predominance of the condition this might be expected to enhance slightly the separation of z values between patients and controls, although the incidence of the condition in previously unaffected individuals is probably <1 in 50.

The calculation of linear discriminant function (z values) for patients and controls is shown in *Figure 3*. It should be noted that 65 per cent of patients achieved z values in excess of any z values seen in control subjects.

It can be seen that using the cut-off point of 253 it is possible to classify correctly 28 of the 35 controls (80 per cent) and 53 of the 62 patients (85 per cent). This is a better predictive result that that seen in Study 1 but is of a similar order.

Discussion

Previous studies on onychocryptosis have concentrated on the affected toe. It is evident from this study that distortions in the anatomy occur owing to the disease process and that measurements taken from such toes would reflect those distortions. Significant differences were detected between the right and left toes of patients for cross-sectional area and nail fold width. Therefore, only patients with unilateral disease were included in the study, thereby allowing measurements to be made from the unaffected toe. This obviated the source of error created by distortions due to the disease process. This was clearly important in the design of the study because it was anticipated that anatomy would be significant in determining risk of developing the disease. The finding of significantly thinner nails, thicker nail folds and a greater prevalence of medial rotation in the normal toes of patients compared with controls confirmed the importance of this aspect of study design.

The patients studied were found to be similar to those studied by other authors such as Lloyd-Davis and Brill[2] with regard to age, male predominance and involvement of the lateral nail fold. The majority of patients were in the 16–25-year age group and male patients outnumbered female patients by 2:1, confirming that this is primarily a disease of young men. The involvement of the lateral fold in 72 per cent of patients is similar to the frequency of 84 per cent described by Fowler[5] and suggests a mechanical or anatomical predisposition. Such predispositions were reinforced by a history of previous episodes of ingrown nail in 30 per cent of the patients.

In view of the large number of parameters meriting investigation it was necessary to control this study by studying an age and sex-matched group of healthy patients who had never

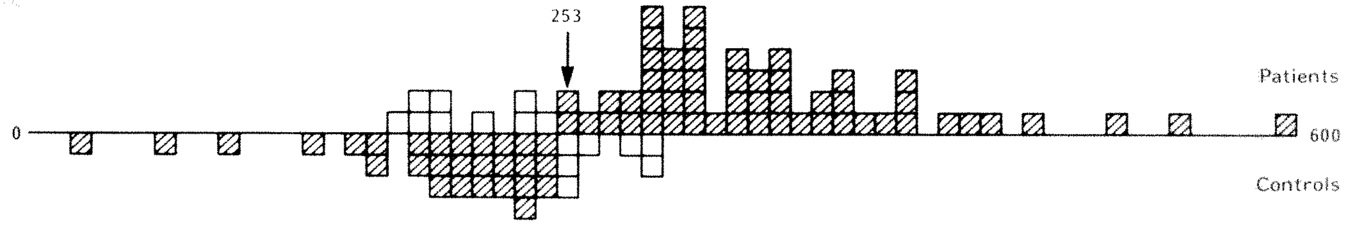

Figure 3 *Distribution of linear discriminant function (z) values, Study 2. The discriminating variables are nail fold width, nail thickness and medial rotation of the big toe. Controls: 28 (▨) with a z value <253, (80 per cent), seven (□) with a z value >253; patients: 53 (▨) with a z value >253 (85 per cent), nine (□) with a z value <253*

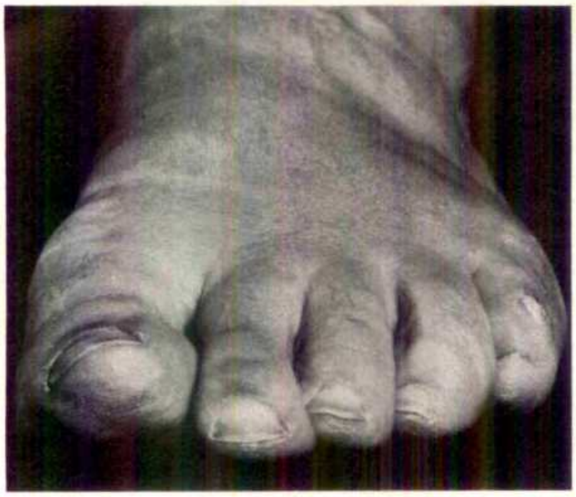

Figure 4 *Anterior view of left foot (adult female) showing medial rotation of the great toe occurring during weight bearing*

suffered with onychocryptosis. The possibility that the control group may contain subjects who would subsequently develop ingrown nail was considered. The incidence of the disease is difficult to ascertain but Clarke and Dillinger[1] found an incidence of 2·9 per cent in infantrymen. As these were all men and a recognized high-risk group it is unlikely that more than 1 in 50 of the controls would subsequently suffer from the disease. Consideration was also given to whether the presence of a diseased toe on one foot might place excessive load on the unaffected foot and distort the toe anatomy or influence medial rotation. Medial rotation was not affected by this, being consistently either present or absent in both great toes of patients. The effect of weight bearing on nail fold width is unlikely to be significant. The great toes take little weight when standing and the additional load which occurs during limping is transferred largely to the heel. Limping is uncommon in patients with ingrown nail; most patients experience pain only if footwear is rubbing or if the toe suffers direct trauma.

A family history of the condition in first- and second-degree relatives was twice as common in patients as in controls, suggesting a familial nail or toe shape. This was reinforced by the statistically significant differences in nail fold width and nail thickness between the unaffected toes of patients and those of controls. Patients tended to have wide, fleshy nail folds and thin nail plates.

The incorporation of correlation between variables and the use of stepwise multiple regression analysis identified three key variables that were significantly different between the two groups: nail fold width, medial rotation of the great toe, and nail thickness. These results were clearly indicative of an anatomical predisposition combined with the presence of medial rotation in patients. Such an anatomical situation would explain the occurrence of the condition during weight bearing when the thin nail plate could erode the nail fold, particularly if a sharp edge were produced by faulty nail cutting. It would also explain why the disease is so frequently recurrent and intractable and why total nail avulsion without nail bed destruction frequently leads to a recurrence of the ingrown nail because this procedure does not remove either underlying risk factors. The disappearance of the disease with increasing age would be expected for a variety of reasons such as effective treatment or increased thickness of the toe nail with age.

The anatomical predisposition would also explain the effectiveness of surgical treatments such as wedge resection of the nail folds, practised by Vandenbos and Bowers[6], and removal of a longitudinal strip of nail adjacent to the affected fold followed by localized cautery of the nail bed at the base of the nail strip. The latter procedure, described by Murray and Robb[10], is less traumatic than either a wedge resection of the folds[6] or a wedge resection involving both a strip of nail and some of the nail fold, as described by Palmer and Stevenson[11]. All three procedures reduce the nail/nail-fold contact in such patients and therefore medial rotatory motion would not roll the nail fold across the nail plate during walking.

Medial rotation of the great toe is present while weight bearing and absent while the foot is off the ground. It therefore means that there is repetitive medial rotation and derotation with every footstep in walking. This movement would cause the nail to move in relation to the lateral nail fold which would be inhibited from movement by contact with the adjacent toe. This would explain the high preponderance of lateral fold involvement and why a thinner nail plate that has been cut correctly or incorrectly may penetrate the nail fold. *Figure 4* illustrates the effect of medial rotation on the lateral nail fold.

The use of linear discriminant function analysis to provide the best separation between patients and controls, using nail fold width, nail thickness and medial rotation as discriminating variables, allowed the derivation of an equation with a high level of predictive ability. This equation provides a numerical value by substitution of three simple measurements. The nail thickness at the central point of the free edge of the nail and the nail fold width can be measured by use of Vernier callipers and the presence of medial rotation can be assessed during weight bearing.

In order to consider the possibility of using the equation as a predictor in high-risk groups such as police cadets or infantry, it was necessary to validate the model in a further group of patients and controls. The second phase of the study was conducted by independent observers and resulted in a very similar distribution of linear discriminant function values for patients and controls, classifying 80 per cent of controls and 85 per cent of patients correctly.

This study provides a rationale for less traumatic surgical approaches to ingrown nail than nail avulsion with or without nail bed ablation. Removal of a nail strip with ablation of the related nail bed is frequently adequate. It may also be valuable to be able to identify subjects at high risk of this disabling condition so that they could be educated to avoid trigger factors such as excessive walking.

Correspondence to:
Mr S. A. Jenkins

In a planned sequential policy for the emergency control of continued bleeding from oesophageal varices, oesophageal transection was performed after failure of conservative treatment, including injection sclerotherapy. In 15 patients who underwent emergency oesophageal transection, bleeding was controlled by operation in the majority (87 per cent), but 11 of the 15 patients died in hospital. Mortality in patients with poor liver function (Child's C) was 100 per cent, the majority of deaths resulting from hepatic and renal failure. The results of this study suggest that emergency oesophageal transection to control acute variceal haemorrhage is associated with a poor prognosis in patients with poor liver function and questions its role in a sequential emergency treatment policy.

Keywords: Variceal haemorrhage, injection sclerotherapy, emergency oesophageal transection

In recent years it has become increasingly clear that injection sclerotherapy, either alone or in combination with vasoactive drugs and balloon tamponade, is effective in controlling acute variceal haemorrhage in approximately 95 per cent of patients[1–5]. However, when sclerotherapy fails to control bleeding or prevent its early recurrence, it is essential to identify other forms of treatment which can be employed in sequence. Surgical intervention, which is now rarely used as an initial treatment for bleeding varices, is usually called upon when sclerotherapy fails. Because portal systemic shunting carries high operative mortality and morbidity rates when undertaken as an emergency, especially in patients with poor liver function[6,7], most surgeons would choose oesophageal transection to control the bleeding. In these circumstances, operation is performed after the patient has been bleeding for some time and the results of operative intervention at this stage in treatment may not be as good as when initiated earlier. We report our experience with oesophageal transection, in a planned management policy, for patients in whom bleeding could not be controlled by resuscitation, conservative treatment and injection sclerotherapy.

Patients and methods

Between January 1980 and December 1986, 127 patients presented with their first variceal haemorrhage (index bleed) and were treated primarily by injection sclerotherapy. This treatment was administered either on admission, in which case it was usually the sole treatment, or within a few hours when on many occasions preliminary control was attempted with vasopressin or balloon tamponade. In all but eight of these patients (94 per cent) bleeding was controlled. In addition, 54 patients who experienced recurrent variceal haemorrhage on a maintenance sclerotherapy programme were admitted to hospital; in 47 (87 per cent) control was achieved. In eight patients with an index bleed and seven patients with recurrent variceal bleeds (interval bleeders), haemorrhage could not be controlled by conservative treatment. Oesophageal transection was carried out using an EEA stapling gun (Auto Suture Company, UK) inserted into the oesophagus via a small gastrostomy[8,9]. The clinical data of the 15 patients who underwent oesophageal transection are shown in *Table 1*.

Operation

The technique was essentially that described by Johnston[10]. Usually the abdomen was opened through a midline epigastric incision and intra-abdominal vascular adhesions divided between ligatures. The left lobe of liver was mobilized by incising the left triangular ligament and the abdominal oesophagus was mobilized by incising the overlying peritoneum. Vagal trunks were identified and tapes passed around each. Large paraoesophageal varices around the lower 10 cm of the oesophagus were individually ligated and divided to provide extrinsic devascularization. The left gastric vascular axis was identified and ligated in continuity by two separate linen threads. Where feasible, veins around the upper part of the stomach were ligated, along with the short gastric veins, to extend the extrinsic devascularization. A stout linen thread was passed round the abdominal oesophagus, within (i.e., to exclude) the taped vagal trunks. Through a small gastrostomy in the upper third of the anterior wall of the stomach an EEA stapler (No. 27) was inserted into the stomach, and the head passed into the oesophagus to ensure that the ligature, when tightened onto the shaft of the stapler, would be at, or just above, the cardio-oesophageal junction. After the ligature was tied, the head of the stapler was closed and fired. After the removal of the stapler the gastrostomy was closed in two layers.

Results

The in-hospital mortality rate of oesophageal transection used in this particular therapeutic sequence was 11 out of 15 patients (73 per cent) (*Table 2*). Bleeding recurred in two patients (13 per cent) and therefore postoperative recurrent haemorrhage did not constitute a problem.

Table 2 *Complications and outcome of the 15 patients undergoing oesophageal transection*

Patient	Child's classification	Complications	Outcome
1	A	None	Survived
2	A	None	Survived
3	B	None	Survived
4	B	None	Survived
5	C	Continued bleeding, cardiac arrest	Died day 1
6	C	Liver failure	Died day 1
7	B	Adult respiratory distress syndrome	Died day 11
8	C	Liver failure	Died day 8
9	C	Liver failure	Died day 16
10	C	Liver and renal failure	Died day 8
11	C	Liver and renal failure	Died day 2
12	B	Cardiac and respiratory arrest	Died day 29
13	C	Liver and renal failure	Died day 14
14	C	Continued bleeding, progressive liver failure	Died day 32
15	C	Liver and renal failure	Died day 6

The transfusion requirements of the four patients who survived the operation (12·5 ± 7·32 units, range 4–20) was less than that of those who died postoperatively (22·2 ± 10·9 units, range 6–41), but the difference did not achieve statistical significance ($P = 0{\cdot}13$).

The majority of deaths following oesophageal transection resulted from progressive hepatic and renal failure. Survival was closely related to liver function at the time of operation as assessed by Child's grading. Neither of the two patients in Child's group A died, of the four patients with Child's B grading, two (50 per cent) died while in hospital. All of the nine patients in Child's C grade died in hospital (100 per cent). Of the 11 patients who died following oesophageal transection, gross ascites was present in nine and hepatic encephalopathy in six. Of the patients who survived the operation none displayed evidence of hepatic encephalopathy before the operation, but two had mild ascites. The hospital mortality rate of the Child's C patients whose bleeding was controlled by conservative tratment and who did not require oesophageal transection was 44 per cent (21/48) for the first-time bleeders and 46 per cent (13/28) for interval bleeders.

Laboratory data other than those included in the Child's grading were not especially helpful in predicting outcome (*Table 3*). Of the haematological parameters the only significant difference between the groups was in the platelet count, survivors having significantly higher counts than those who died. The concentrations of total bilirubin, urea and creatinine were lower, and albumin levels were significantly higher, in the four patients who survived the operation than in the 11 patients who died. There were no significant differences in the plasma levels of liver enzymes, total protein, globulin or direct bilirubin between the two groups of patients.

Of the four patients who survived oesophageal transection two have not experienced further variceal haemorrhage (5 years in one patient, 9 months in one patient) and in both no further varices have been observed at follow-up gastroscopy. The two remaining survivors have both experienced recurrent variceal haemorrhage. The first of these patients presented with an acute variceal bleed 7 months after oesophageal transection and was successfully treated initially with injection sclerotherapy. However, the patient continued to have severe recurrent variceal bleeding, and approximately 9 months after transection underwent an elective portacaval shunt from which she made an uneventful recovery. The second patient experienced a massive upper gastrointestinal haemorrhage approximately 3 years after oesophageal transection and died at another hospital before he could be resuscitated.

Discussion

For the control of acute variceal haemorrhage, injection sclerotherapy has pride of place and operation is usually restricted to those in whom injection sclerotherapy and other measures, e.g. somatostatin, have failed. The results of this study show that surgery, placed later in a sequential treatment policy, is associated with a high death rate, related more to poor liver function than to complications of operation or recurrence of bleeding.

Until recently procedures involving a direct attack on the varices were relatively unsuccessful particularly in western countries, because of a high rate of recurrent bleeding or of leakage at the oesophagogastrointestinal anastomosis. However, oesophageal transection using an EEA stapling device is a technically simpler operation and, since it does not seem to affect liver blood flow, should not theoretically impair liver function or precipitate hepatic encephalopathy. Moreover, further surgical procedures such as portasystemic shunt are not precluded. Consequently, transabdominal oesophageal transection is widely advocated for the treatment of oesophageal varices.

Emergency portasystemic shunting is highly successful in controlling bleeding, but the price is prohibitively high mortality[6,7]. Moreover between 20 and 30 per cent of patients who survive the operation can be expected to develop hepatic encephalopathy[11,12]. There are, therefore, few surgeons who would advocate shunting as an initial treatment for variceal haemorrhage.

The timing of oesophageal transection remains debatable. Our own experience and that of Johnston[10] show that oesophageal transection carries a much lower mortality under elective circumstances than in an emergency. However this difference in outcome, related to the timing of treatment, is found with any therapy for bleeding oesophageal varices. There are those who advocate oesophageal transection much earlier in the therapeutic sequence. The results of several trials comparing oesophageal transection to injection sclerotherapy as the primary initial treatment are awaited with interest. However, despite its simplicity, oesophageal transection remains a more formidable procedure than injection sclerotherapy and is therefore unlikely to have a place as initial treatment when the patient is admitted to hospital with the first haemorrhage. Most clinicians have recourse to oesophageal transection when initial conservative measures have failed, but the outcome in these circumstances, at least in our experience, is bleak.

Variceal haemorrhage which does not respond to conservative measures is frequently associated with a poor prognosis for several reasons—irreversible shock, aspiration pneumonia, hepatic failure and complications of treatment. Oesophageal transection was successful in controlling bleeding in most of the

Table 3 *Laboratory data of patients surviving or dying after emergency oesophageal transection*

Urea (mmol/l)	2·98 ± 0·15	13·64 ± 2·65*
Creatinine (mmol/l)	48·15 ± 14·5	91·2 ± 9·65*

Results are expressed as mean ± s.e.m., * denotes a significant difference between the groups ($P < 0{\cdot}05$). KCCT, kaolin and cephalin clotting time; γ-GT, γ-glutamyl transferase patients but the hospital mortality rate was 73 per cent. In this series death was associated mainly with hepatic impairment. In most of these patients there was clear evidence before operation of dysfunction of the liver and impaired hepatic reserve as measured by the Child's classification. There may also be a degree of renal impairment since the plasma creatinine levels of the patients who died after transection were significantly higher than those of the survivors. These findings are consistent with other reports on the use of emergency oesophageal transection in the treatment of uncontrollable variceal bleeding, where the prognosis for the patient with poor hepatic function is extremely poor[13–18]. Consequently we believe that the effectiveness of emergency oesophageal transection in the patient whose bleeding cannot be controlled by conservative means is limited and that good results can be anticipated only in those patients with good, or slightly impaired, liver function (Child's A and B grades).

The problem remains about what to do with high risk patients who continue to bleed after injection sclerotherapy. Certainly, since blood loss and transfusion are poorly tolerated by the cirrhotic patient, surgical treatment should be instituted as early as possible to prevent the deterioration that is inevitably associated with prolonged conservative management. Even so, although the evidence is somewhat limited, the results of randomized controlled clinical trials published to date suggest that early oesophageal transection does not greatly improve the survival of patients with poor liver function[19–21] Alternatively more powerful vasoactive agents, e.g. somatostatin[22], or more vigorous injection sclerotherapy may control bleeding, even temporarily, in those high risk patients, allowing for a more definitive procedure to be undertaken electively when the patient is more suitable for operation. The latter suggestion is supported to some extent by the present study in which the mortality rate of Child's C patients whose bleeding was controlled by conservative means. including injection sclerotherapy was 44 per cent in first-time bleeders which, although high, is considerably better than the 100 per cent mortality rate in those who continued to bleed who underwent oesophageal transection Therefore there is circumstantial evidence that even in those with severe liver impairment (Child's C) the prognosis is better when bleeding is brought rapidly under control.

Mr T. Bates

When prophylactic antibiotics are used in abdominal surgery it is customary to give the first dose before the operation. Whilst intra-operative antibiotics may be effective in elective surgery, there may be an advantage to starting pre-operatively when there is already an infective focus such as appendicitis. Antibiotics started pre-operatively (group P) have been compared with antibiotics started after initial abdominal exploration (group T). Three intravenous doses of 500 mg metronidazole plus 1 g cephazolin were given in a randomized, double-blind study of 700 emergency and elective high-risk abdominal operations. Antibiotic plasma concentrations at the end of the operation were significantly lower in group P but lay well within the therapeutic range. Wound infection rates, which included minor and delayed infections, were similar in both groups (group P, 57 of 342, 16·7 per cent; group T, 55 of 358, 15·4 per cent; 95 per cent confidence intervals for the difference being −4·1 to +6·7 per cent. In appendicitis, wound infection rates were 12·1 and 13·9 per cent for groups P and T respectively. However, non-fatal deep sepsis was more common in group P (nine cases) than in group T (two cases) ($\chi^2 = 4·9$, $P < 0·05$). Postoperative infection was twice as common in obese patients whose body mass index (BMI) was ≥ 26 (39 of 132, 30 per cent) than in thin patients whose BMI was <24 (41 of 288, 14 per cent; $\chi^2 = 13·8$, $P < 0·001$). This study failed to show any advantage to starting antibiotics pre-operatively, even in appendicitis.

Keywords: Metronidazole, cephazolin, prophylaxis, laparotomy, wound infection, intra-abdominal sepsis, lengths of stay, obesity

When prophylactic antibiotics are used in abdominal surgery it is widely accepted that the first dose should be given pre-operatively[1,2] and this view stems from the experimental work of Burke[3]. Stone and his colleagues[4] have confirmed that postoperative antibiotics are ineffective and, in a critical review of the literature on prophylactic systemic antibiotics, Chodak and Plaut considered any study in which therapy was not begun pre-operatively to be inadequate[5].

The giving of an antibiotic is sometimes overlooked in the preparation for emergency surgery until an unexpected focus of sepsis or soiling is found at operation. There is considerable evidence that antibiotics are effective when given intra-operatively[6] and even when they are placed in the wound at the end of the procedure[7,8].

Pre-operative intravenous cephaloridine has been compared with a similar dose placed in the wound at the end of laparotomy and although no overall difference was found there did appear to be an advantage to the earlier treatment in appendicitis[9]. Brumfitt and Hamilton-Miller[10] have made a plea for further studies into the timing and duration of prophylactic antibiotics and the present study was undertaken to determine the optimum time of administration of the first dose.

It was decided to use three doses of antibiotics since the effectiveness of this regimen is established[11–14] and to use the agents cephazolin[4,15,16] and metronidazole[17–21] which are well tried in abdominal surgery to cover both aerobic and anaerobic organisms[22,23].

Wound infection rates have been compared in a randomized double-blind trial of antibiotics started pre-operatively and antibiotics started after initial abdominal exploration in patients undergoing emergency or at-risk abdominal operations.

Patients and methods

Eligibility

All patients aged ≥ 16 years in one of the two surgical firms of a district general hospital having emergency abdominal operations, repair of strangulated hernias or elective colorectal operations were included. Elective cholecystectomy was included if one or more of the following criteria were present· age >65 years, jaundice, rigors within 1 week, previous biliary surgery, planned exploration of the common bile duct[24]. Elective gastroduodenal operations were included if one or more of the following criteria were present carcinoma of the oesophagus or stomach, gastric ulcer, pyloric stenosis, bleeding ulcer, current treatment with ranitidine or cimetidine[1]

Exclusions (before randomization)

Patients were excluded if they were known to be allergic to penicillin or either of the agents used, if the operating surgeon considered that pre-operative antibiotics were essential, or if the patient had received antibiotics within the previous week

Trial design

Trial packs contained three doses of each of two antimicrobial agents. They were consecutively numbered and arranged from a table of random numbers to contain placebo drugs for either the pre-operative dose or for the intra-operative dose (*Table 1*)

The antibiotics

Each patient received three active doses of 500 mg metronidazole intravenously over 20 min plus 1 g cephazolin as an intravenous bolus,

0007-1323/89/010052-05$3.00 © 1989 Butterworth & Co (Publishers) Ltd

the first dose being either pre-operative (group P) or intra-operative (group T). The pre-operative dose was given at the same time as the routine premedication. The placebo doses were prepared to resemble the respective active drug so that the clinical investigators were unaware of the composition of any pack.

Losses

All eligible patients who were not entered into the trial (i.e. were not randomized) were recorded and the completeness of records was cross-checked against the operating theatre record book.

Withdrawals (after randomization)

Those patients who were ineligible on the protocol were withdrawn (e.g. if antibiotics had been given within 1 week pre-operatively or if the patient had a cholecystectomy without a stated risk factor). If the operation was cancelled or if the delay after the pre-operative dose was greater than 12 h, patients were also withdrawn from the study.

Missing data

The following patients were not withdrawn after randomization. Dose violations were recorded if protocol antibiotics were omitted or delayed. Some patients had additional antibiotics either in continuity with the trial doses or after an interval. The operative findings did not always necessitate opening a viscus, e.g. in disseminated malignancy, but these patients were not withdrawn. Patients with missing data were included in the study.

Concentrations of antimicrobials in plasma

In 21 patients plasma concentrations of metronidazole and cephazolin were measured on induction of anaesthesia, and then at hourly intervals for 3 h. The concentrations of metronidazole and cephazolin in each plasma sample were determined simultaneously by high performance liquid chromatography. To each plasma sample (100 μl) was added methanol (200 μl) containing the internal standard, 9048 RP (the 2-ethyl analogue of metronidazole). After mixing, the samples were allowed to stand in the dark at room temperature for 4 days. After mixing and centrifuging, aliquots of the supernatant were injected into the chromatograph. The analytical column (internal diameter 15 cm × 4·6 mm) contained Hypersil ODS (Shandon Southern Products, Ltd., Runcorn, UK) (3 μm), and the mobile phase consisted of 0·01 M aqueous potassium dihydrogen phosphate (pH 3·0), methanol and acetonitrile in the proportion of 93·12:3 volume/volume, respectively, at a flow rate of 1·1 ml/min. The compounds of interest were detected in the column eluate by their ultraviolet light absorbance at 300 nm. The retention times were about 4·5 min for metronidazole and about 7·0 min for cephazolin. The coefficients of variation of the method for each drug were <10 per cent at 1 and 10 μg/ml for metronidazole, and 5 and 50 μg/ml for cephazolin, with limits of detection of about 0·5 μg/ml for metronidazole and 2 μg/ml for cephazolin.

Follow-up

All patients who did not have a wound infection whilst in hospital were seen about 1 month after operation. They were asked if there had been any discharge from the wound after they left hospital and if this information was missing from the outpatient notes they were subsequently contacted by telephone or letter.

Risk factors

The following variables were considered: age, sex, body mass index (BMI = weight in kg/(height in metres)^2), diagnostic category (*Table 2*), degree of peritonitis (*Table 3*), grade of surgeon, interval from pre-operative dose to operation, duration of operation, dose violations, and severe sepsis found at operation considered to require continuation of antibiotics after the protocol doses (continuous antibiotics).

* Deaths within 24 h, excluded for means

Outcome events

The outcome was assessed as follows Wound sepsis was categorized as major, minor or late (criteria of Pollock and Evans[25]) and deep sepsis was recorded separately The causes of death within 30 days were categorized as septic, sepsis-related (e.g. mesenteric infarction) or not septic (e g terminal malignancy, even if at home) The number of postoperative days in which fever was noted to be >37·5°C was recorded Postoperative infection requiring antibiotics (interval antibiotics) was considered an outcome event. Length of postoperative hospital stay included the day of discharge but not the day of operation Formal outcome evaluation of each patient was completed and agreed between at least two authors before the double-blind code was broken.

Consent

The trial protocol was approved by the district ethical committee and all patients signed consent to the investigation after verbal and written explanation

Estimation of required sample size

In order to make an estimate of the number of patients required in each arm of the study to avoid a type II error (the conclusion that there is no difference between two groups when a real one exists), the following assumptions were made. The proportion of events was estimated to be 20 per cent and a clinically important reduction would be from one-third to 13 per cent Using Feinstein's formula[26,27] with α 0·05 and β 0·20, it was calculated that 437 patients would be needed in each arm of the trial

Statistical methods

Data were analysed on an RM Nimbus PC2 (Research Machines, Oxford, UK) microcomputer using SL microstatistical software (Questionnaire Service Company, East Lansing, USA). This enabled comparison of risk factors and outcome events The χ^2 test was used to compare wound infection and deep sepsis rates in the two groups and the extremes of BMI Approximate 95 per cent confidence intervals were calculated for the difference between the groups in respect of wound infection. Drug concentrations in the two groups were compared using the Mann–Whitney *U* test because the data were highly skewed

Results

There were 750 eligible patients available for the study between Februrary 1982 and March 1986. Over the same period, 75 otherwise eligible patients were excluded: 58 patients had had antibiotics within 1 week; in 12 patients pre-operative antibiotics were considered essential; 3 patients were allergic to penicillin; and 2 patients refused consent. There were 33 losses of eligible patients, for 9 of whom there were no trial drugs available and the remainder were forgotten. There were 17 withdrawals after randomization, 8 of which were unavoidable due to a cancelled or postponed operation and the remainder were entered but ineligible There were therefore 700 evaluable patients, being 93 per cent of those eligible and 98 per cent of those entered into the trial.

Wound infection

The overall wound infection rates were similar in both groups, being 16·7 per cent in group P and 15·4 per cent in group T (*Tables 2* and *4*). The 95 per cent confidence intervals for the difference are from −4·1 to +6·7 per cent. Nineteen per cent of wound infections occurred at home, mostly after appendicectomy. Major wound infection, which often delayed discharge from hospital, occurred in just under 10 per cent of patients in both groups.

Comparison of risk factors and outcome

The two groups were well matched for diagnostic categories (*Table 2*) and severity of appendicitis (*Table 3*). There were, however, twice as many patients with generalized or faecal peritonitis in group P. Furthermore, there were four patients with fatal mesenteric infarction in group P and none in group T. The mean age in the 2 groups was similar (*Table 5*) but there were 12 more patients aged ≥80 years in group P. This was a serious imbalance since 18 of the 35 deaths were in patients of this age.

There were twice as many deaths in group P, five of which occurred within the first 24 h compared with one in group T. Of those surviving more than 1 day, eleven deaths in group P were sepsis-related and eight in group T There was a higher incidence of non-fatal deep sepsis in group P (nine cases) compared with group T (two cases; $\chi^2 = 4{\cdot}9$, $P < 0{\cdot}05$).

Of the 11 patients with deep sepsis, 5 had a BMI ≥26. Rather more patients in group T had a BMI ≥26 (*Table 5*). Of 132 patients with a BMI ≥26, 39 had a sepsis-related outcome (30 per cent) compared with 14 per cent of the 288 with a BMI <24 ($\chi^2 = 13{\cdot}8$, $P < 0{\cdot}001$; *Table 6*).

There were more patients in group T with a delay between the pre-operative dose and the start of operation but in this group the first dose was placebo. No correlation was found

Table 5 *Risk factors compared between the intra- and pre-operative groups*

	Group T (intra-operative)	Group P (pre-operative)
Total number of patients	358	342
Age ≥80 years	32 (9%)	44 (13%)
Age (mean ± s.d.)	53 ± 22 years	55 ± 22 years
Men	172	169
BMI (mean ± s.d.)	23 ± 4	23 ± 4
BMI <24	140 (39%)	148 (43%)
BMI ≥26	73 (20%)	59 (17%)
Sepsis at operation (not appendicitis)	27 (11%)	40 (17%)
Registrar operation	155	156
Interval first dose to operation >3 h	25	10
Duration of operation >3 h	47	48
Dose violation (omitted or delayed)	14	11
Continuous antibiotics	10	10

Missing data excluded in percentage calculation (16 for T, 26 for P); BMI, body mass index

Table 6 *Body mass index compared with sepsis-related outcome*

BMI*		Sepsis-related outcome†	
Value	No. patients	No. patients	%
≥26	132	39	30‡
≥24 but <26	238	45	19
<24	288	41	14‡
Unknown	42	—	—

* BMI, body mass index (weight/height^2); † sepsis-related outcome = wound infection, deep sepsis, septic death or sepsis-related death; ‡ χ^2 test comparing highest and lowest infection rates ($\chi^2 = 13·8$, $P < 0·001$)

between the pre-operative interval and any of the outcomes examined.

There were more patients in group P with persistent fever, prolonged postoperative stay and receiving therapeutic antibiotics (*Table 4*). The overall mean duration of postoperative fever and length of stay was, however, similar in both groups.

There was no obvious association between grade of surgeon and outcome. Patients whose postoperative course was complicated by hospital wound infection, deep sepsis, septic death and sepsis-related death were more likely to have had a longer operation than those whose course led to non-septic death or who had delayed or no wound infection. Patients with deep sepsis or hospital wound infection stayed much longer in hospital and had more days of fever than other patients Therapeutic antibiotics were used in three of the nine septic deaths, one of the sepsis-related deaths and four other patients with wound infection. There was no obvious association between dose violation and outcome.

Microbiological isolates

Details of the micro-organisms isolated are available on application to the authors.

Follow-up

Seventeen patients (2·4 per cent) were lost to follow-up with regard to delayed wound infection, nine of whom died from malignancy within 4 months.

Missing data

The most common missing data were measurements of patients' height so that BMI was not calculated for 16 patients in group T (4·5 per cent) and 26 in group P (7·6 per cent).

Fate of withdrawals

There were eleven withdrawals in group T and six in group P, of whom three in each group did not have an operation. One patient in group T, who was withdrawn because the operation was delayed for 36 h after the first dose, died from an anastomotic dehiscence following left hemicolectomy. One patient in group P who was withdrawn because she had had pre-operative antibiotics was found to have an inoperable carcinoma of the ovary and had a minor postoperative wound infection. She left hospital but died within 30 days. There was no other complication amongst the withdrawals.

Concentrations of antimicrobials in plasma (Figure 1)

Concentrations of metronidazole were significantly higher in group T than in group P at 1, 2 and 3 h after induction of anaesthesia whilst cephazolin levels were higher at 1 and 2 h ($P < 0·05$, Mann–Whitney U test). However, concentrations of the two antibiotics remained well within the therapeutic range (4 times the mean inhibitory capacity) for the expected organisms in both groups throughout the 3-h period. Concentrations of metronidazole declined only slightly in 3 h, whereas those of cephazolin more than halved

Discussion

This study failed to show any advantage to starting prophylactic antibiotics pre-operatively in abdominal surgery, even in appendicitis[9] where this could be regarded as treatment rather than prophylaxis[28].

It is difficult to explain why the patients receiving pre-operative antibiotics (group P) appeared to have a higher incidence of non-fatal deep sepsis. It is possible that the lower plasma levels of cephazolin at the completion of operation may have been important, but these concentrations lay well within the therapeutic range in the few cases tested. Furthermore, there was no relationship between the length of the interval from the pre-operative dose to the intra-operative dose and the outcome. There is no suggestion from this study that giving antibiotics with the premedication is of any advantage and it seems likely that a high plasma and tissue concentration at the time of operation is the most important factor.

The slow decline in the plasma concentrations of metronidazole compared with those of cephazolin is consistent with the long plasma elimination half-life of metronidazole of around 8 h[29], whereas that for cephazolin is much shorter, in the range 1–3 h[30]. The trial design meant that in group T the second and third antibiotic doses were sometimes given only 4 h apart, which for metronidazole was unnecessary. The intervals, however, were chosen in order to avoid giving a large number of placebo doses. When these drugs were given pre-operatively a better estimate of elimination half-life could be made than in group T patients, where drug distribution as well as elimination would be occurring in part of the 3-h period under study. The values obtained for their plasma elimination half-life are similar to those reported in the literature for healthy ambulant individuals. It can therefore be tentatively concluded that a major operation and the underlying disease have virtually no effect on the elimination of either of these drugs.

Obesity has been shown to be a risk factor for wound infection in abdominal surgery[31,32] but a consideration of this

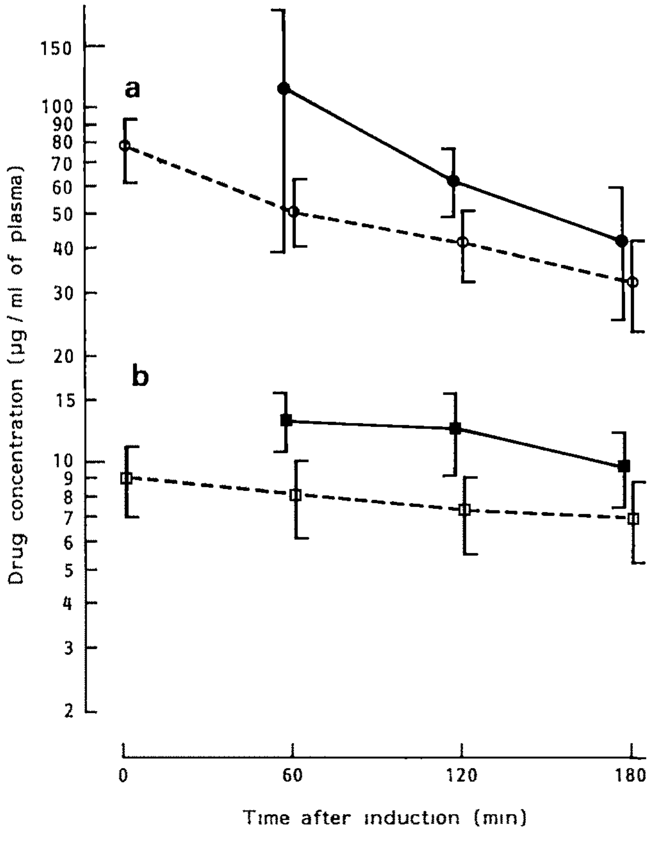

Figure 1 *Mean (±s.d.) plasma levels (µg/ml) of* **a** *cephazolin and* **b** *metronidazole in patients given intravenous cephazolin (1 g) and metronidazole (500 mg) pre-operatively (– – –) or intra-operatively (——). Pre-operative group P, n = 11, intra-operative group T, n = 10*

factor is often omitted from clinical trials comparing wound infection rates. BMI (Quetelet's index)[33] was found to be a sensitive discriminator.

The wound infection rates in this study are much higher than have been reported by Matheson's group[34,35] and, although a few others[36] have managed to achieve such low rates, it seems likely that greater attention to the prevention of intra-operative soiling and possibly the addition of antibiotic peritoneal lavage may be beneficial. It is difficult to be certain that we have not come to rely too heavily on powerful systemic antibiotics and are less meticulous with peritoneal toilet and wound protection.

The number of evaluable patients in this study fell short of the estimated sample size by 20 per cent but wound infection rates were so close in the two groups that if there is a real advantage to giving antibiotics pre-operatively it seems most unlikely that it would ever be demonstrated by increasing the size of the study Whilst it is possible that these results carry a type II error in that real differences in outcome may have been missed in relatively small subgroups, it is unlikely that there is a clinically important advantage to giving antibiotics with the premedication rather than during the course of operation for patients requiring abdominal surgery.

Posterior sagittal anorectoplasty for reoperation in children with anorectal malformations

A. J. L. Brain and E. M. Kiely

*Hospital For Sick Children,
Great Ormond Street,
London WC1N 1EH, UK*

Correspondence to:
Mr A J. L. Brain

A prospective study was carried out in 12 consecutive patients (7 boys and 5 girls), to evaluate posterior sagittal anorectoplasty for patients incontinent of faeces after anorectal reconstruction. Examination revealed anatomical problems such as: recurrent fistula (two), massive urethral diverticulum (one), absent vagina (one), and a missed urogenital sinus (one). Preliminary electromyography showed the external sphincter to be displaced from the anus in nine patients. Posterior sagittal anorectoplasty, with correction of anatomical defects and precise reconstruction of bowel within the sphincters, was carried out after the formation of a loop colostomy. No postoperative complications were observed. Contrast studies confirmed healed suture lines before stoma closure. Follow-up, between 4 and 46 months, revealed good faecal control in only two patients, with a significant improvement in two others. The rest remained incontinent although sensation was improved. These disappointing results, at variance with other published reports, lead us to conclude that posterior sagittal anorectoplasty, when used as a secondary procedure, is good for correcting anatomical defects but not for improving faecal continence.

Keywords: Posterior sagittal anorectoplasty, anorectal anomalies, faecal incontinence

Incontinence of faeces following surgery for supralevator anorectal anomalies remains a problem. More than one-third of patients may have a poor result[1]. This may be due to misplacement of bowel in relation to the muscles of continence, or to pathology such as a recurrent fistula. Reoperation may be difficult with a disappointing outcome. However, several authors have reported good results using a posterior sagittal approach as a salvage procedure for failed primary surgery[2–4]. This approach gives excellent exposure and has led to a clearer understanding of the surgical anatomy. Pena[4] has even claimed that posterior sagittal anorectoplasty (PSARP) as a secondary operation is easier than when the same operation is carried out as a primary procedure. For these reasons we set up a prospective study to evaluate PSARP for the salvage of patients incontinent of faeces after anorectal reconstruction.

Patients and methods

A consecutive series of twelve children (five girls and seven boys), whose faecal incontinence after previous surgery for anorectal anomalies made them socially unacceptable, were included in the study Their ages ranged from 5 to 17 years (median 11 years). All seven boys and one of the girls had been born with a supralevator anorectal anomaly with a fistula Primary surgery, as listed in *Table 1*, had been carried out in the first year of life. Two girls who were born with a cloaca had had a primary abdominoperineal pull through. The other two girls had been diagnosed as having a vestibular ectopic anus. One had a neonatal cutback and the other an anal transposition at the age of 6 years.

Before presentation and inclusion in this study, eight of the twelve children had already had one or more unsuccessful attempts at secondary surgery This included various types of anoplasty, proctoplasty and levatorplasty. One boy had a 'redo' pull through (*Table 1*)

Table 1 *Patients, defects and previous surgery*

Patient	Sex	Age (years)	Anomaly	Primary procedure*	Salvage procedures
1	M	8	High ARA	Abdominoperineal pull through	None
2.	F	7	Vestibular ectopic anus	Transposition	Repair rectovaginal fistula
3	M	13	High ARA	Abdominosacral anal pull through	Levatorplasty Secondary levatorplasty
4.	F	14	Cloaca	Abdomino-anal pull through	None
5.	M	17	High ARA	Anorectal pull through	Proctoplasty
6.	F	16	High ARA	Abdominoperineal pull through (at age 12 years)	Anal reconstruction with skin
7.	F	7	Vestibular ectopic anus	Anal cut back	Hendren anoplasty
8	M	15	High ARA	Abdominosacroperineal pull through	Anoplasty Levatorplasty
9.	M	10	High ARA	Sacro-abdomino-anal pull through	'Redo' pull through
10.	M	14	High ARA	Pull through	Levatorplasty
11.	M	10	High ARA	Abdominoperineal pull through	None
12.	F	5	Cloaca	Abdominoperineal pull through	None

ARA, Anorectal anomaly; * primary procedure as described by the surgeon who carried out the operation

0007–1323/89/010057–03$3.00 © 1989 Butterworth & Co (Publishers) Ltd

At presentation all patients were completely incontinent of faeces with minimal sensation and no control.

Assessment included thorough clinical examination, under anaesthesia if necessary, as well as needle electromyography of the pelvic floor and anal sphincters In nine children electromyography showed the anal sphincter to be displaced from the anus Neuropathic changes were identified in two. Examination showed the pelvis and/or perineum to be extensively fibrosed with anorectal stenosis in six patients. A massive urethral diverticulum, representing the fistula remnant, was found in one boy with recurrent urinary tract infections. One girl was found to have an absent vagina In another the urethra was found to enter a urogenital sinus. A recurrent recto-urethral and a rectovaginal fistula were found in two other children. Two of the twelve patients in the series were found to have a sacrum with only three segments

A loop colostomy was formed either before or at the time of the PSARP. A thorough mechanical preparation of the bowel was carried out with washouts, and clear fluids by mouth for 48 h before operation. A single dose of broad spectrum antibiotics (ampicillin, gentamicin and metronidazole) was given on induction of anaesthesia. The operation was carried out in the manner described by Pena and deVries[5,6] through a posterior sagittal approach, with tapering of the bowel and relocation within the reconstructed sphincters. After the operation a contrast study was carried out via the distal limb of the stoma to confirm healing. The anus was calibrated with Hegar's dilators to ensure an adequate calibre, between 12 and 16, depending on the size of the child. In ten children the stoma was subsequently closed between 3 and 7 months postoperatively. In one patient the stoma was closed after only 3 weeks because of social pressure as he lived abroad and would be unable to return for further surgery In another child, stoma closure was postponed until 14 months after PSARP, because of impending school examinations

Results

No early postoperative complications were observed. Suture lines healed without infection and without clinical or radiological evidence of a leak. Colostomy closure was carried out in all 12 children without morbidity. They have been followed up for between 4 and 46 months (median 30 months). In only four children have there been any improvements in faecal control. Two of these are now completely continent. They have good sensation with only occasional staining and no frank incontinence. The other two are much improved with good sensation but imperfect control. An improvement in sensation was observed in four of the eight others However all eight children still have socially unacceptable incontinence of faeces (*Table 2*).

The posterior sagittal approach was found to give excellent exposure allowing correction of the anatomical defects. No recurrence of the anorectal stenoses, the massive urethral diverticulum, the recto-urethral or the rectovaginal fistulae has been observed. The absent vagina was successfully reconstructed One patient was found to have mild anal stenosis with circumferential prolapse, 6 months after operation. The stenosis was not severe, was easily dilated and has not recurred 3 months later. In the girl with a urogenital sinus, some breakdown was noted between the newly constructed urethra and vagina On follow-up, 13 months after surgery, she was found to have greatly improved urinary continence.

Discussion

We found that only two of the twelve patients became socially continent of faeces following PSARP. Two others were much improved These results are disappointing when compared with other published reports.

The literature on the posterior sagittal approach for failed primary surgery is scanty. However published reports to date show encouraging results. As early as 1971 Stephens and Smith[2], 'using an operative approach similar if not identical to that termed posterior sagittal'[3], reported a good functional improvement in continence in seven out of ten patients. deVries[3] reported good results using PSARP for reoperation in two children, both of whom became socially continent. Similarly in a series of eight patients, reported by Pena[4], five had an immediate 'excellent' result with continence of faeces and no soiling. The other three were much improved but did still have occasional involuntary bowel actions.

Our disappointing results may be due to either the operation in our hands, or to the patients in our series. The actual operative technique was very similar to that demonstrated by Pena (personal communication). The postoperative management was different. Pena recommends a strict regimen of dilatation[6,7] We did not routinely carry this out. Pena lists the factors that may influence the final result of PSARP as a salvage procedure[4]. These are: the original anatomy (height of the malformation and sacral anomalies); magnitude of damage at previous procedures; and age, intelligence, education and family environment. It is of note that the damage at previous procedures in our series was extensive. At least six of our patients had very severe fibrosis, reflecting the severity of the complications following the previous surgery. This may be the reason for our poor results when compared with other series. Surprisingly, one of the two patients with a good result was also found to have severe fibrosis at operation. Of our two patients with a short sacrum, one had a good result, contrary to Pena's findings. We have incomplete data on the height of the original fistulae in our patients There is no reason to suspect that they were different from those in other series. Two of the girls in our series had primary surgery for low anorectal anomalies. The results of PSARP for salvage in these patients were as bad as in those with a high anomaly. The patients in our series were of a similar age to those in other series. There is no reason to suspect that their intelligence, education, or family environment were any different either.

Table 2 *Findings, salvage procedure and results*

Patient	Findings	Salvage procedure	Follow-up (months)	Faecal continence
1.	Urethral diverticulum, sphincter behind anus	Excision of diverticulum, PSARP	30	Incontinent
2	Rectovaginal fistula, dense fibrosis, sphincter behind anus	Fistula closed, PSARP	22	Incontinent
3.	Sphincter behind anus	PSARP	34	Incontinent
4	Urogenital sinus, sphincter behind anus	Vaginoplasty, urethroplasty, PSARP	25	Improvement
5	Short sacrum, sphincter behind anus	PSARP	33	Incontinent
6	Frozen pelvis, complete anal stenosis	PSARP with abdominal mobilization of colon	4	Improvement
7.	Wound breakdown, absent vagina, sphincter behind anus	Vaginoplasty, PSARP	20	Incontinent
8.	Severe fibrosis, sphincter behind anus	PSARP	30	Incontinent
9	Dense fibrosis, two rectal strictures, recto-urethral fistula	Strictures resected or divided, fistula closed, PSARP	31	Excellent
10	Sphincter behind anus	PSARP	23	Incontinent
11.	Fibrosis, sphincter behind anus, short sacrum	PSARP	39	Excellent
12.	'Frozen pelvic floor'	Urethroplasty, vaginoplasty, PSARP	46	Incontinent

PSARP, posterior sagittal anorectoplasty

We found the pulled through bowel to lie anterior to the external sphincter complex on pre-operative electromyography in nine of the twelve patients. This finding was confirmed at operation; deVries and Pena report similar findings[3,4].

One patient in our series developed mild anal stenosis. We did not regularly dilate the anus after operation. Pena recommends that this should be done for a minimum of 3 months[6].

Pena and deVries[6] have emphasized the suitability of the posterior sagittal approach for the repair of rectovaginal fistulae and cloacal anomalies. This may be combined with an abdominal mobilization of rectum or vagina when insufficient length is obtained from below In only one of our patients did we have to mobilize the rectum from above. We confirmed Pena and deVries' finding that the posterior sagittal approach allows excellent exposure. It enables more precise identification of the anatomy and hence reconstruction. Heavy retraction is unnecessary. This may have been a significant contributory factor to the lack of postoperative sepsis.

Acknowledgements

We would like to thank Dr Stewart Boyd who performed the electromyography in these patients.

Announcement

Reviews

The Editorial Board of *The British Journal of Surgery* continues to invite review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium of £100. Potential authors seeking advice on the suitability of review topics are advised to contact: Professor D. C Carter, Regius Professor of Clinical Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors invite submissions of signed leading articles to *The British Journal of Surgery*. These articles should be 600–1000 words in length, should address controversial topics of current interest and should be supported by key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium of £100 is payable on publication. Potential authors seeking advice on the suitability of topics are advised to contact: Professor D. C. Carter, Regius Professor of Clinical Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Surgical workshops

The Editors invite the submission of articles describing technical innovations or modifications which may be useful in surgical practice. These articles should be less than 500 words long; they can be accompanied by no more than two figures but should not carry supporting references. Articles submitted to the Surgical Workshop series may be subjected to external review and assessment by the Editorial Board before acceptance.

Case reports

The British Journal of Surgery receives an increasing number of case reports each year. Space within the Journal remains at a premium and the rejection rate is likely to be high. Authors are advised to restrict such reports to a maximum of 500 words, to use no more than five references and to submit no more than one illustration.

Paget's disease of the anus is a rare disorder of controversial origin and is frequently associated with malignancy. We studied eight patients and carried out immunohistochemical studies to determine whether particular functional profiles might be indicators of a malignant association. One patient presented with synchronous carcinoma and two developed carcinomas 3 and 10 years after excision of Paget's disease. Five patients underwent wide local excision and have not developed cancer (median follow-up 6 years, range 5–13 years). However, four patients developed recurrent Paget's disease. Immunohistochemical studies showed that in general Paget cells stained positively with CAM 5.2 (a cytokeratin marker), gross cystic disease fluid protein (a marker for apocrine cells), human milk fat globule glycoprotein (HMFG 1 and 2) and carcinoembryonic antigen but negatively for PR3A5 (a marker for colonic goblet cells). Three cases had a staining profile which was quite different from that usually observed and these were associated with malignancy. One showed an antigenic profile more typical of a large bowel carcinoma. Paget's disease of the anus appears to run one of two clinical courses: to develop malignancy; or to recur locally, often on repeated occasions. Wide local excision is the treatment of choice but long-term follow-up is necessary because of the cancer risk. An immunohistochemical staining pattern which is different from usual may indicate a higher malignant risk and/or identify some cases of Paget's disease as representing a downward 'pagetoid' extension from a anorectal adenocarcinoma rather than a true epidermotropic apocrine neoplasm of the perianal skin.

Keywords: Extramammary Paget's disease, immunohistochemistry

Paget's disease of the anus is a rare perianal disorder of unknown aetiology. The first report was by Darier and Couhllaud in 1893[1], 19 years after Sir James Paget first described the characteristic breast lesion[2]. It has been postulated that extramammary Paget's disease is: a sweat gland carcinoma[3]; an intraepidermal metastasis of adenocarcinoma usually of sweat gland origin[4], a multicentric local process[5]; or a special type of squamous carcinoma[6]. The list of putative cell types of origin for Paget cells is equally varied: primitive multipotential epidermal cells[7], melanocytes[8], keratinocytes[9] and cells of both eccrine and apocrine sweat glands[10,11]. Recent work has supported the view that Paget cells in extramammary Paget's disease are of glandular origin, as they contain low molecular weight cytokeratins and carcinoembryonic antigen (CEA)[12–14]. Furthermore their apocrine nature is indicated by the expression of gross cystic disease fluid protein (GCDFP) antigen[15,16].

Paget's disease of the anus is reported as being associated with a fairly high risk of malignant change either at presentation or at a later date. In a recent literature review, Beck and Fazio[17] showed an overall risk of associated malignancy of 73 per cent. In their own ten patients, three had invasive cancer at the time of presentation and a further two developed cancer during follow-up. Five other patients remained disease-free after wide local excision, although the follow-up period was a median of only 2 years (0·4–4·2 years). Williams *et al.*[18] reported associated cancer in five of their seven patients. The remaining two patients underwent multiple wide excisions for recurrent disease over the following 12 and 17 years respectively, emphasizing the need for long follow-up.

Paget's disease of the anus raises questions with regard to: the cell type of origin, whether the disease represents a low-grade malignancy or is a sign of synchronous cancer, and whether there is a method that can identify individuals who are at risk of developing malignancy. We have undertaken a study of patients who have been treated for Paget's disease of the anus at St. Mark's Hospital with the aim of identifying clinical and immunohistochemical differences which might distinguish between those who develop malignant change and those who remain free from invasive cancer. In particular, we have considered the possibility that Paget's disease may represent two quite distinct entities: (i) an epidermotropic neoplasm arising from perianal apocrine glands; and (ii) downward 'pagetoid' spread by signet ring cells stemming from an anorectal adenocarcinoma.

Patients and methods

A review was made of the case notes of eight patients treated at St Mark's Hospital with a histological diagnosis of perianal Paget's disease at the time of treatment. They included four patients previously reported in 1977 by Lock *et al.*[19], one of whom has also been reported separately[20,21]. Particular attention was paid to the incidence or subsequent development of malignancy and recurrence of Paget's disease in those patients who did not develop malignant disease.

Histological sections of the eight cases of Paget's disease were prepared and stained with haematoxylin and eosin for pathological review. Six cases of signet ring cell carcinoma of the rectum were included in the study, one of which was associated with downward pagetoid spread involving the perianal skin. Serial sections were stained for the presence of mucins by means of Alcian blue at pH 2·5, PAS-diastase and PB/KOH/PAS[22]. Additional levels were cut and processed by an immunoperoxidase technique using monoclonal antibodies recognizing a low molecular weight cytokeratin (CAM 5.2)[23], other glandular epitopes, human milk fat globule glycoprotein (HMFG) 1 and 2[24] and CEA (C46)[25] (kindly donated by Amersham International plc,

UK), a mucinous epitope expressed by colorectal goblet cells (PR3A5)[26] and an apocrine marker, GCDFP (BRST.2, CRL Cambridge Research Laboratories, UK)[15,16] An indirect immunoperoxidase technique with the avidin–biotin detection system (Amersham International plc) was employed. Antibodies were undiluted except for CEA (1.5) and GCDFP (1:40). Antibodies were from authors in references where no commercial source is given All sections were reviewed by a single pathologist (J.R J.) who was unaware of the clinical details and scored for the presence or absence of the particular marker.

Results

Patients

There were six women and two men with a median age of 75 years (55–85 years). The median follow-up period was 6 years (0·5–13 years). Six presented with perianal soreness and two with a lump. Symptoms had commonly been present for some time with a median of 6 months (4–48 months). The eight patients fell into two groups: those with malignancy either at the time of presentation or on follow-up (three patients) and those who remained free from invasive cancer (five patients).

Details of the three patients with associated malignancy are shown in *Table 1*. Only one patient (A) had malignancy at presentation. She was treated with fast neutron radiotherapy and survived a further 8 years; she died from carcinomatosis at the age of 93 years. Two patients (B and C) developed tumours at 3 and 10 years respectively after their initial presentation. Patient B was treated by radiotherapy for a squamous carcinoma of the tongue 2 years before presenting with a pelvic mass from which he died 2 months later. Patient C died from widespread disease 3 years after a bilateral block dissection for inguinal nodes containing poorly differentiated carcinoma. The latter patient has been the subject of two previous case reports[20,21].

Five patients (*Table 2*) did not develop cancer but four of them developed recurrent Paget's disease. Four patients are

under follow-up with Paget's disease of whom two have symptomatic recurrence and two are free from disease.

Histological studies

The amount of mucus varied between cases but was often less than that seen in signet ring carcinoma. The mucins were positive with PAS-diastase and Alcian blue (pH 2·5) but gave only a weak reaction or no reaction with PB/KOH/PAS. In contrast, three of six signet ring cell carcinomas were intensely positive with PB/KOH/PAS. The latter provided the only qualitative difference in the mucus histochemistry of Paget's disease and signet ring cell carcinoma

In six cases the Paget cells were strongly positive for cytokeratin, supporting their glandular origin. GCDFP was clearly positive in four cases and negative in four, three of the latter being cases A, B and C described in more detail below. CEA was present in most Paget cells but absent in cases A and E. Most Paget cells were positive for HMFG 1 and 2 but so were the majority of signet ring cell carcinomas though less intensely so With the exception of patient A, Paget cells were negative for PR3A5 whereas four signet ring cell carcinomas were positive In case A the PR3A5-positive cells resembled signet ring cells cytologically, and were negative for HMFG 1 and 2 and GCDFP. This patient had a synchronous anorectal mucinous carcinoma. In patient B, who developed a pelvic mucinous carcinoma 3 years after Paget's disease of the anus had been diagnosed, the Paget cells expressed a functional profile as that usually seen with Paget's disease, with the exception of GCDFP which could not be detected. In patient C the Paget cells had large pleomorphic nuclei and secreted no mucus. The poorly differentiated carcinoma which involved the inguinal lymph nodes showed similar cytology CEA and CAM 5.2 were the most strongly expressed antigens. GCDFP was not detected and HMFG 1 and 2 staining was indefinite and weak respectively. The details of the staining reactions are shown in *Table 3*.

Discussion

Paget's disease of the anus is rare At a specialist colorectal hospital there have been only eight documented cases since 1930. It has been said that the condition has a very high association with malignancy—as high as 86 per cent in some series[5]. In our study three of eight patients had associated malignancy, a figure lower than in previous reports, an apparent discrepancy which may have a number of explanations. Firstly, there may be a selection bias towards the association in the smaller series. Secondly, foci of carcinoma in Paget's disease may be small and overlooked, though our specimens were well sampled and examined with care. Finally, the pathological diagnosis is not easy. In particular Paget's disease needs to be distinguished from pagetoid spread by signet ring cells originating from an underlying anorectal adenocarcinoma. We believe that the latter phenomenon may have led to an inflated estimate of the risk of invasive malignancy. Our observations may help to clarify some of the difficulties posed by the pathological diagnosis.

We agree with the concept that Paget cells are of glandular and probably of apocrine origin. Five of our cases had what we would describe as a usual pattern of staining for Paget's disease, that is positive for cytokeratin[12,13], GCFDP[15,16], CEA[14] and HMFG 1 and 2[24] but negative for PR3A5[25]. These patients have not developed malignancy at a median follow-up period of 8 years. However they have a high recurrence rate which would support a hypothesis that Paget's disease is a low grade though often multicentric neoplastic change within the skin as suggested by Helwig and Graham[5].

Three cases had a staining pattern which differed from that described above and they were all associated with malignancy. In particular none expressed the apocrine marker GCDFP. In patient B, the mucinous adenocarcinoma of the pelvic region which developed did not show any particular histological resemblance to an apocrine tumour, and in case C the cytological atypia and marked differences in staining compared with typical Paget's disease might reflect an enhanced aggressiveness. On the other hand, patient A, where the staining pattern was completely different from the other cases (negative for all markers except PR3A5), almost certainly did not have Paget's disease at all but was an example of pagetoid spread from an anorectal mucinous adenocarcinoma. The Paget cells in this case were characterized by an abundance of intracytoplasmic nuclei and a small, hyperchromatic eccentric nucleus. Thus they resembled signet ring cells cytologically

Turning to the management of the condition, it seems that unless the patient is very frail the treatment of first choice is wide local excision with or without skin grafting. However four of our five patients who did not develop invasive malignancy did suffer from local recurrence, often on multiple occasions over a long time period. This is similar to the experience of Williams *et al.*[18] Beck and Fazio[17] have a much lower recurrence rate and they ascribe this to their policy of wide local excision with quadrant biopsy, and frozen section confirmation of clearance. However their follow-up period is short with a median of 2 years. Clearly a long follow-up is necessary both to assess recurrence and malignant potential. If, as in our experience, the disease is locally recurrent then it may be necessary to consider adjuvant therapy such as radiotherapy or topical/systemic chemotherapy. However, it must be remembered that some patients may live a long time with their disease requiring only symptomatic treatment.

In conclusion, this rare disease continues to pose problems in diagnosis and treatment. However the use of special staining may assist in the separation of genuine Paget's disease from pagetoid spread due to an anorectal adenocarcinoma. This would be an important distinction, with implications for patient management.

Acknowledgements

We thank the consultants of St Mark's Hospital for allowing us to report these cases and Dr Jean Ritchie for her help in identifying the patients. We are grateful to the technical staff of the Histopathology Department of St. Mark's Hospital for performing the immunohistological staining.

Anorectal function after abdominal rectopexy: parameters of predictive value in identifying return of continence

K. Yoshioka, G. Hyland and M. R. B. Keighley

Department of Surgery, The General Hospital, Birmingham, UK

Professor M R. B. Keighley, The Clinical Teaching Block, The General Hospital, Steelhouse Lane, Birmingham B4 6NH, UK

Posterior abdominal rectopexy was performed in 12 patients with a full-thickness rectal prolapse: 9 had faecal incontinence. The prolapse was successfully controlled in all cases and six of nine patients were rendered continent. Physiological studies in patients were compared with age- and sex-matched controls. Preoperative anal pressures were significantly lower than in controls at rest (R), during maximum pelvic floor contraction (Sq) and attempted defaecation (St) (R, $P<0\cdot005$*; Sq,* $P<0\cdot005$*; St,* $P<0\cdot005$*). Anorectal angles were significantly more obtuse in patients than in controls (R,* $P<0\cdot05$*; St,* $P<0\cdot025$*). None of these parameters changed significantly after abdominal rectopexy. Median rectal emptying significantly decreased after operation (preoperative 83 per cent/min; postoperative, 58 per cent/min,* $P<0\cdot05$*). Median perineal descent during attempted defaecation also significantly decreased after operation (preoperative, 8·5 cm; postoperative, 7·1 cm;* $P<0\cdot025$*). Parameters which predicted return of continence included: delayed leakage during the saline infusion test* ($P<0\cdot025$)*, a narrow anorectal angle during pelvic floor contraction* ($P<0\cdot025$)*, minimal pelvic floor descent during contraction* ($P<0\cdot05$)*, and a long anal canal at rest* ($P<0\cdot05$) *and during pelvic floor contraction* ($P<0\cdot025$).

Keywords: Abdominal rectopexy, anal canal pressure, perineal descent, pelvic floor descent, anorectal angle

Rectal prolapse is a distressing condition, not only because of the uncontrollable prolapse but because approximately two-thirds of these patients are also incontinent[1]. Many patients with rectal prolapse have exaggerated perineal descent[2] and the pudendal nerve may be damaged by prolonged straining[3].

Rectal prolapse can be successfully treated by posterior abdominal rectopexy[4–7] with a low rate of recurrence but faecal incontinence may persist in 30 per cent of patients despite an effective rectopexy[8]. We have undertaken paired physiological studies in 12 consecutive patients before and after Marlex® (C. R. Bard Incorporated, Massachusetts, USA) posterior abdominal rectopexy Results have been compared with age- and sex-matched controls to detect the functional abnormalities associated with a rectal prolapse. Paired studies have allowed us to identify those patients who are likely to remain incontinent after rectopexy and in whom an additional pelvic floor repair might be indicated.

Patients and methods

Twelve patients with a full-thickness rectal prolapse underwent posterior abdominal rectopexy as previously described[4] using polypropylene (Marlex) mesh between May 1982 and June 1987 All patients were women and had a median age of 57 years (range, 22–79 years) Clinical and physiological evaluation was carried out before and 3–6 months after operation Physiological studies were compared with 15 age- and sex-matched control patients (all women, median age 54 years (range, 32–73 years)) who had no gastrointestinal disease

Anal canal and sigmoid pressures were measured simultaneously at 2, 4 and 26 cm from the anal verge in the seated position on a specially designed chair. Manometry was performed using a water-perfused 4-channel catheter with side openings connected to a pressure transducer (Lectromed Ltd , UK) and multichannel recorder (MultiTrace 4, Lectromed, Ltd.). The catheter was introduced into the sigmoid colon with the patient in the left lateral position The position of the catheter was checked radiographically in five patients to establish the manometric characteristics of a blocked catheter. The catheter was fixed to the left buttock by tape Pressures were measured at rest, during maximum pelvic floor contraction and attempted defaecation. Rectal compliance and the rectoanal inhibitory reflex were assessed using a rectal balloon attached to the 4-channel catheter and positioned in the rectal ampulla just above the levator ani The balloon was also connected to a pressure transducer and pen recorder Intraballoon pressure responses to incremental 50 ml increases in intrarectal volume were measured over the range 0–400 ml of air Rectal compliance was calculated by dividing the increase in balloon volume by the pressure inside the balloon Reduction of more than 10 per cent of the resting anal pressure was recorded as an intact rectoanal inhibitory reflex.

Rectal sensation was assessed using the same rectal balloon Three parameters of sensation were recorded according to the criteria of Farthing and Lennard-Jones[9]· threshold volume, volume associated with constant rectal sensation and the volume below 400 ml at which pain became intolerable (maximum tolerable volume) In some patients a volume of 400 ml caused no apparent discomfort, but further volumes were not introduced for fear of bursting the balloon

The saline infusion test was designed to test liquid continence. A 4-channel polyvinyl catheter (external diameter 5 mm) with side openings at 2, 4, 19 and 26 cm from the anal verage was inserted into the sigmoid colon. The catheter was connected to pressure transducers and a multichannel recorder so that the pressures at 2, 4 and 26 cm from the anal verge could be recorded while isotonic saline was being infused The patient was seated on a special chair and a total of 1500 ml isotonic saline (37°C) was infused at a rate of 50 ml/min by means of a peristaltic pump (H R Flow Inducer, Watson–Marlow Ltd , UK) The patient was instructed to retain the saline for as long as possible without leakage A commode was placed under the seat to collect any fluid that leaked from the anus The volume infused at the time of the initial leak and the total volume retained were recorded Basal and peak pressure[10] were measured at 2, 4 and 26 cm from the anal verge during saline infusion

Electromyography of the pelvic floor was recorded using a concentric needle electrode Electrical activity was recorded at rest, during maximum pelvic floor contraction and during attempted defaecation

The anorectal angle, pelvic floor descent, perineal descent and anal canal length were measured from radiographs or frozen frames taken

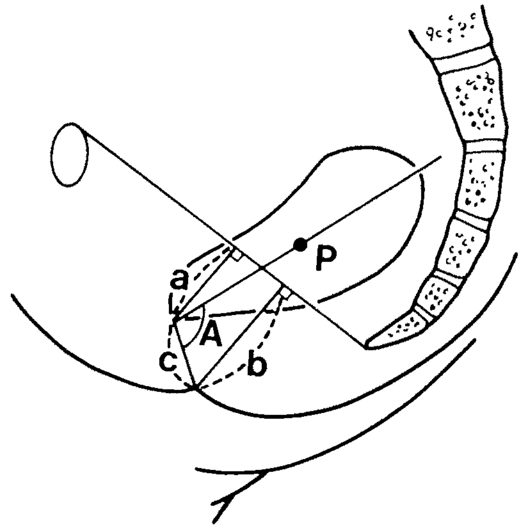

Figure 1 *Assessment of proctogram pelvic floor descent (a), perineal descent (b), anal canal length (c), centroid (P), anorectal angle (A)*

during videoproctography. The patient was seated on a lavatory pan after introducing 100 ml (120 g) of Baritop (Concept Pharmaceuticals, UK) mixed with cellulose, to achieve a consistency similar to that of normal faeces. The anorectal angle was measured as the angle between the luminal axis of the anal canal and the axis of the rectum This was assessed at rest, during maximum pelvic floor contraction and during attempted defaecation using an image intensifier linked to a video screen. The long axis of the rectum was obtained by drawing a line through the anorectal junction and the 'centroid' of the rectum. The centroid was defined as the point at which a line running from the anorectal junction could divide a lateral projection of the rectum into two equal areas. The centroid was determined by a mathematical formula programmed to analyse lateral radiographs using a BBC microcomputer. Pelvic floor descent was defined as the perpendicular distance between the pubococcygeal line and the anorectal junction The perpendicular distance between the pubococcygeal line and the anal verge was measured as perineal descent. Anal canal length was the distance between the anorectal junction and the anal verge (*Figure 1*).

Rectal emptying was assessed during videoproctography by asking the patient to evacuate as much of the introduced contrast material as possible during 1 min The result was expressed as a percentage of the amount of material infused.

As these data were not normally distributed, statistical analysis of the physiological data was made using the Mann–Whitney *U* test These studies had the approval of the local ethical committee. Patients gave consent for the studies after written explanation that any predictive parameters would allow a more rational approach for future surgical treatment The controls were studied concurrently using the same techniques

Results

The rectal prolapse was successfully controlled by rectopexy in all cases. Neither full-thickness rectal prolapse nor mucosal prolapse was observed during the 8–24 months (median, 14 months) of follow-up. Complete continence was achieved after rectopexy in six of the nine patients with incontinence Three patients remained incontinent and three patients developed constipation after the operation. Those patients who remained incontinent had a median age of 69 years (range, 61–77 years) compared with 57 years (range, 25–79 years) in those whose continence was restored.

Anal canal pressures 2 cm from the anal verge at rest, during maximum pelvic floor contraction and attempted defaecation were 50 (21–80), 79 (33–121) and 71 (36–100) cmH$_2$O (median and range) before operation and were significantly lower than in the controls in all positions (control data: at rest, 86 (53–113); maximum pelvic floor contraction, 129 (60–171); attempted defaecation, 100 (53–179) cmH$_2$O, median and range, $P<0{\cdot}005$ respectively). However, there were no significant changes after operation (*Figure 2*). Preoperative pressures 4 cm from the anal verge were significantly lower than control values during maximum pelvic floor contraction (62 (38–98) *versus* 91 (41–169) cmH$_2$O, median and range, $P<0{\cdot}005$) and attempted defaecation (77 (38–127) *versus* 112 (55–198) cmH$_2$O, median and range, $P<0{\cdot}01$) but not at rest and no significant changes were observed after operation.Pressures at 26 cm from the anal verge did not differ significantly from control values and did not change significantly after operation.

Threshold volume, volume associated with constant sensation and total tolerable volume were 100 (50–150), 200 (100–200) and 350 (200–400) ml (median and range) respectively before operation. These values did not differ significantly from control values and did not change after operation. Mean rectal compliance in patients was: 9·18 (4·29–20·00) ml/cmH$_2$O and did not differ from controls (13·15 (5·94–26·92)) or change significantly after rectopexy (7·89 (5·45–16·00)).

The rectoanal inhibitory reflex was observed in all controls but was absent in four patients with rectal prolapse. Absence of the rectoanal inhibitory reflex persisted in all four cases after successful rectopexy. Increased electromyographic activity in the puborectalis muscle was observed in 2 of 15 controls, and in 2 patients before operation. This response persisted in both patients and was observed for the first time in another patient after rectopexy.

The volume at which saline first leaked and the total tolerable volume of saline were 60 (5–1500) and 100 (0–1500) ml (median and range) respectively before operation. These values were significantly lower than controls (first leak, 800 (80–1500), $P<0{\cdot}005$; total tolerable volume, 1000 (100–1500) ml, $P<0{\cdot}005$) but did not change significantly after operation (first leak, 120 (30–1500); total tolerable volume, 120 (20–1500)). Anal canal pressures 2 cm from the anal verge during the first 5 min of the saline infusion were significantly lower than control pressures for all three parameters ($P<0{\cdot}005$) but no significant changes were observed after operation (*Table 1*). Pressures at 4 and 26 cm from the anal verge during saline infusion did not differ significantly from those of controls and did not change after operation.

Preoperative anorectal angles at rest, during maximum pelvic floor contraction and attempted defaection were 124 (109–151), 110 (91–152) and 140 (112–196) degrees (median and range) respectively. These angles tended to be more obtuse than in controls and were significantly different at rest (124 (109–151) *versus* 112 (85–134) degrees, $P<0{\cdot}05$) and during attempted defaecation (140 (112–196) *versus* 134 (88–149) degrees, $P<0{\cdot}025$). However, there were no significant changes after operation (*Figure 3*).

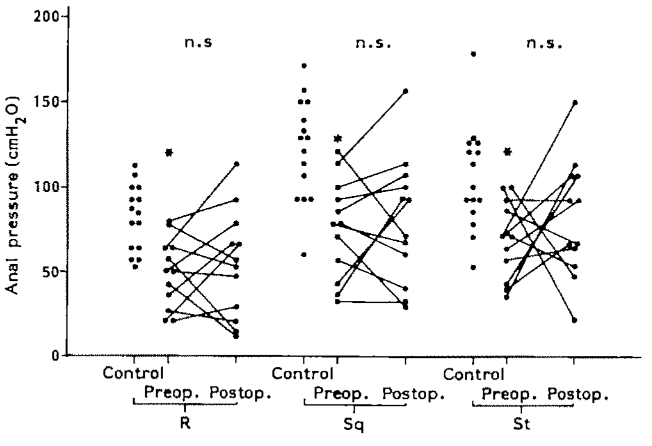

Figure 2 *Anal pressure 2 cm from the anal verge before and after rectopexy and compared with controls R, at rest, Sq, during maximum pelvic floor contraction, St, during attempted defaecation, *P<0 005, preoperative* versus *control, n.s., no significant difference observed after rectopexy*

Table 1 *Pressures at 2 cm from the anal verge during the first 5 min of the saline infusion test in controls and rectopexy patients*

			Rectopexy patients		
	Controls ($n = 15$)		Preoperative ($n = 12$)		Postoperative ($n = 12$)
Maximum basal pressure	79 (14–136)	$P < 0.005$	36 (14–50)	n.s.	43 (20–107)
Minimum basal pressure	43 (0–129)	$P < 0.005$	21 (7–43)	n.s.	29 (13–79)
Peak pressure	107 (36–193)	$P < 0.005$	64 (29–114)	n.s.	64 (36–150)

Values are median and range (cmH_2O)

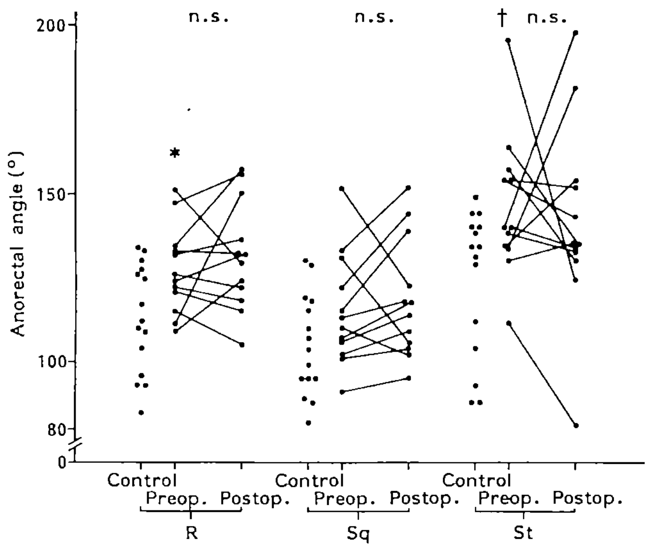

Figure 3 *Anorectal angles before and after rectopexy and compared with controls. R, at rest, Sq, during maximum pelvic floor contraction, St, during attempted defaecation,* *$P < 0.05$, †$P < 0.025$, *preoperative* versus *control, n.s., no significant difference observed after rectopexy*

Pelvic floor descent, perineal descent and anal canal length in controls and in patients before and after rectopexy are shown in *Table 2*. Preoperative anal canal length tended to be shorter in patients than in controls but this was statistically significant only during attempted defaecation ($P < 0.05$). Pelvic floor descent and anal canal length did not change significantly after operation, whereas perineal descent tended to become shorter after operation, this parameter only changed significantly during attempted defaecation ($P < 0.025$).

Percentage median rectal emptying was 83 per cent/min (range, 42–100) before operation compared with 75 per cent/min (range, 0–100) in controls ($P < 0.05$). Rectal emptying significantly decreased to 58 per cent/min (range, 0–100) after rectopexy ($P < 0.05$) when compared with preoperative levels.

When the six incontinent patients whose continence was restored were compared with the three who remained incontinent, volume at first leakage was significantly greater in patients who became continent (80 ml, range, 40–300) than in those who did not (30 ml, range, 10–40: $P < 0.025$). Preoperative median anorectal angles were more acute in patients whose continence was restored than in those who were not, the difference being statistically significant during pelvic floor contraction (*Table 3*)

Preoperative median pelvic floor descent was less in patients whose continence was restored than in those who remained incontinent, but this was statistically significant only during maximum pelvic floor contraction (*Table 4*). Preoperative median anal canal length was greater at rest and during contraction in patients who became continent than in those who did not (*Table 5*). Median perineal descent tended to be less in patients whose continence was restored in all three positions but the differences were not statistically significant

No significant differences were observed in patients whose continence was restored compared with those who remained incontinent with respect to pressures at 2, 4 and 26 cm from the anal verge, rectal sensation, rectal compliance, rectoanal inhibitory reflex, electromyography, and pressures during saline infusion or rectal emptying

Discussion

Full-thickness rectal prolapse may be successfully treated by posterior abdominal rectopexy. Despite successful treatment of the rectal prolapse, faecal incontinence persists in about a third of patients[4,6,7]. In this study three of nine incontinent patients were not improved by rectopexy. Chronic constipation is also recognized as a complication of rectopexy and three of 12 patients developed constipation in this study[11].

Physiological studies showed significant differences between patients and controls in that patients had lower anal canal pressures, earlier leakage during the saline infusion test with lower tolerable volumes, lower anal pressures during saline infusion, more obtuse anorectal angles and shorter anal canal length. These results are hardly surprising as three-quarters of the patients had associated faecal incontinence[8]. Read *et al.*[12] showed that the volume at first leak and the volume retained during the saline infusion test were significantly lower in patients with incontinence than in controls. Anorectal angles are reported to be more obtuse in incontinent patients than in controls[12,13] and we concur with these findings The rectoanal inhibitory reflex was absent in four patients, but present in all controls. Absence of the reflex has also been observed in constipated patients who do not have Hirschsprung's disease[14]. One possible reason for absence of the reflex is the low basal anal pressure especially when measured using a water-perfused catheter.

There were no significant changes in the physiological parameters that were studied after operation except for the extent of perineal descent and rectal emptying. After operation, descent decreased significantly during attempted defaecation. Decreased perineal descent may have been because of recovery of the pelvic floor muscles and the influence of rectopexy in preventing rectal descent and the associated intussusception.

The decrease in rectal emptying may have been due to improvement in continence as contrast rapidly leaked preoperatively; however there was no significant difference between the median rectal emptying in patients after operation and controls. The fact that rectal emptying is delayed after rectopexy suggests that some automatic denervation might occur following rectal mobilization.

Preoperative values for the volume at first leakage of saline, anorectal angle, pelvic floor descent and anal canal length were significantly different between patients whose continence was restored and those who remained incontinent. We accept that there is a wide scatter in some of these parameters; nevertheless,

Table 5 *Anal canal length in patients with rectal prolapse associated with faecal incontinence*

	All patients ($n=9$)	Continence improved ($n=6$)		Continence not improved ($n=3$)
R				
Preoperative	3·6 (1·2–6·2)	3·7 (3·6–6·2)	$P<0·05$	2·3 (1·2–3·1)
Postoperative	2·3 (1·1–4·9)	2·1 (1·1–4·9)		3·0 (2·3–3·1)
Sq				
Preoperative	4·8 (2·6–6·8)	4·8 (4·3–6·8)	$P<0·025$	3·1 (2·6–4·3)
Postoperative	4·2 (2·3–5·7)	4·1 (3·4–5·7)		5·0 (2·3–5·5)
St				
Preoperative	1·7 (0·1–4·1)	2·9 (0·3–4·1)	n.s.	1·6 (0·1–1·7)
Postoperative	1·3 (0·4–4·0)	1·1 (0·7–4·0)		1·3 (0·4–1·7)

Data shown are median and range (cm); R, at rest, Sq, during maximum pelvic floor contraction; St, during attempted defaecation even in this small cohort of patients, significant differences were detected. The parameters which predicted persistent incontinence were those usually associated in any case with more severe incontinence Some of these features, particularly abnormal descent of the pelvic floor, are thought to play an important role in the pathogenesis of idiopathic faecal incontinence[3,15] causing pudendal nerve damage to the external anal sphincter[16,17]. The importance of identifying parameters which predict patients who are likely to remain incontinent after rectopexy is that these patients might be offered a synchronous pelvic floor repair at the time of rectopexy. It remains to be seen, however, whether this policy increases the morbidity of rectopexy and whether continence might be restored by this approach. It seems likely that the only way to resolve this issue would be to randomize patients who leak saline and who have a short anal canal, obtuse anorectal angles and excessive perineal descent to receive rectopexy alone or rectopexy with pelvic floor repair We believe that the videoproctographic parameters alone will identify the patients in whom an additional postanal repair may be justified at the time of rectopexy.

Fine Needle Aspiration of the Breast

Yolanda C Oertel MD
Professor of Pathology, The George Washington University, School of Medicine, Washington DC, USA.

- ★ **Clearly and concisely written with extensive illustrations including many in colour**
- ★ **Cover all the aspects of the technique from performance to evaluation**
- ★ **Essential reading for surgical pathologists involved in performing aspirations**

Fine needle aspiration is a valuable diagnostic tool that is gaining increased acceptance in the United States. It helps clinicians and surgeons arrive at a more accurate diagnosis in a timely and economical fashion and enhances their ability to manage patients more effectively. This monograph is the product of nine years' experience in which about 10,000 aspirates were interpreted or performed. It covers all aspects of the technique, from performance of the aspiration and processing the specimen, to the evaluation of the information obtained from the procedure. As this experience has shown that results are superior when the aspiration is performed by the pathologist, the emphasis throughout is on the technical aspects of the procedure. The text is extremely well illustrated to facilitate evaluation and differentiation of findings. The result is a clearly written, practical guide to fine needle aspiration of the breast.

Contents

Introduction • Advantages and disadvantages of needle aspiration • Questions asked more frequently • Fine needle aspiration technique • How to succeed at fine needle aspiration • Usual findings in the aspirates • Occasional findings in the aspirates • Benign lesions • Atypical ductal hyperplasia • General diagnostic criteria of malignancy • Adenocarcinomas • Malignant nonepithelial neoplasms • Metastic tumors in the breast • Thoracic wall recurrences and axillary masses • Pitfalls • Fine needle aspiration of nonpalpable breast lesions • Additional diagnostic information • Statistical summary • References • Index

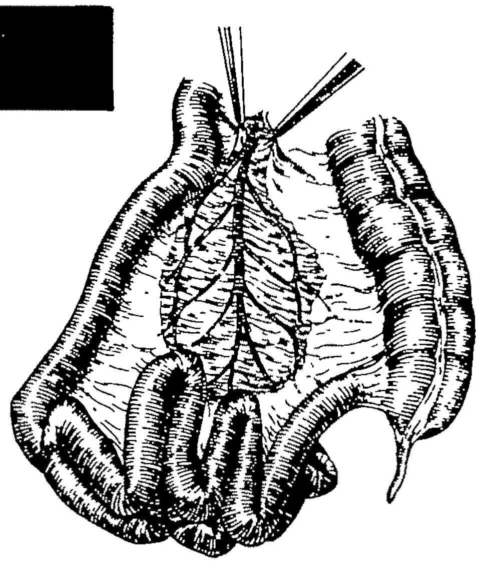
Rob and Smith's Operative Surgery

PAEDIATRIC SURGERY · Fourth Edition



Edited by **Lewis Spitz,** PhD, FRCS
Nuffield Professor of Paediatric Surgery, Institute of Child Health, London,
Consultant Paediatric Surgeon, Hospital for Sick Children, Great Ormond Street,
London, UK.

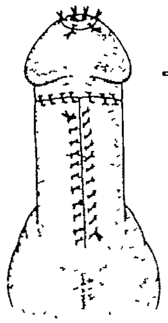
H Homewood Nixon FRCS, FAPP(Hon)
Consulting Paediatric Surgeon, The Hospital for Sick Children, Great Ormond
Street and St Mary's Hospital, Paddington, London, UK.

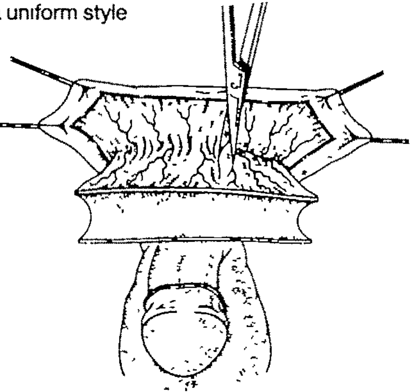
General Series Editors: **Hugh Dudley** Chm, FRCS (Ed) FRACS, FRCS
David C Carter MD FRCS (Ed) FRCS (Glas)
RCG Russell MS FRCS

- ★ **Substantially revised and expanded**
- ★ **Many new contributors**
- ★ **Lavish illustrations with most drawn afresh**
- ★ **Indispensable companion to paediatric surgical practice**

Although much of the material has been largely rewritten and revised, the fourth edition of **Paediatric Surgery** retains the style and high standards which characterize the Operative Surgery Series.

The increased size and scope of the book reflect the rapid development of the specialty over the last few years. The first part consists of new chapters on transport, pre- and postoperative management and anaesthesia, and most other sections, particularly that on the head and neck, also contain new material Within each chapter, the coverage has been broadened to include not only indications for the operation, but also the postoperative complications and statistics on morbidity and mortality. The number of contributors has grown to 65 and the list includes names of leading authorities in the specialty in Britain and around the world. Most of the illustrations have also been redrawn in a uniform style





This comprehensive collection of techniques provides clear and practical advice for all surgeons who operate on children It continues to be an indispensable companion to paediatric surgical practice

Contents: Transport of surgical neonate · Pre- and postoperative management · Paediatric anaesthesia · Head and Neck · Thorax · Abdominal wall · Gastrointestinal tract · Liver and portal system · Neoplasms and endocrine surgery · Urological · Genital · Neurosurgery · Limbs · Trauma · Index

The physiological variation in anal manometry using a perfused catheter with radiating sideholes was studied in 78 healthy volunteers. The maximum intraindividual variation in the length of the anal high pressure zone, resting pressure and squeeze pressure was 10 mm, 26 mmHg and 68 mmHg respectively. The median 95 per cent confidence interval for length of the pressure zone was 4 mm; for resting pressure it was 15 mmHg and for squeeze pressure it was 48 mmHg. Day-to-day variation did not exceed the intraindividual variation. Constant recording with the catheter fixed in the high pressure zone revealed slow waves and ultraslow waves with amplitudes of 6–24 mmHg which could account for most of the intraindividual variation. No sex difference was found in the length of the high pressure zone whereas resting pressure and squeeze pressure were higher in men than in women. Although a tendency towards a decrease in the length of the high pressure zone, resting pressure and squeeze pressure was observed with increasing age, no significant age-related difference could be demonstrated.

Keywords: Anal incontinence, anal manometry, anal physiology

Anal manometry studies in healthy subjects are rather few and knowledge of intraindividual and day-to-day variation and of normal sex- and age-related variation is consequently limited. It has been suggested that the anal canal is shorter and the pressure is lower in women than in men, and that anal canal pressure decreases with age. Most of the data supporting these hypotheses are, however, derived from studies in patients with anorectal disease[1–3].

We present a study of intra- and interindividual variation of anal manometry as well as age- and sex-related variation in subjects with no anorectal symptoms.

Subjects and methods

A total of 58 healthy volunteers (23 men and 35 women) were studied The median age for men was 56 years (range, 30–73) and for women 53 years (range, 28–79). None had any history of gastrointestinal disease or previous anorectal surgery or were using drugs with effect on the gastrointestinal tract No bowel preparation was used.

Investigations were performed with the subject in the left lateral position with flexed knees and hips The manometric system consisted of a low-compliance open-ended perfused polyvinyl catheter with an outer diameter of 2 mm and an inner diameter of 1 mm. The catheter ended in a steel cap with the same external and internal diameter and three sideholes radiating 120°. The catheter was perfused with saline at a flow rate of 0·7 ml/min, and pressure was recorded by a water filled strain-gauge connected to a pen-recorder The manometric system had a pressure rise rate ($\Delta p/\Delta t$) of 800 mm/s.

The probe was introduced manually into the rectum and withdrawn by a machine with a constant speed of 5 mm/s. The length of the anal canal was calculated as the distance from the start of the pressure increase to the point at which pressure fell to zero when the probe left the anal canal. The maximal resting pressure was defined as the highest pressure recorded with the subject relaxed, and the maximum squeeze pressure as the highest pressure recorded during voluntary contraction of the anal sphincter Each investigation was repeated three times, and the mean value was taken as the result.

In another ten subjects (five men and five women) with a median age of 28 years (range, 21–37) anal manometry was performed ten times on the same day and from three to six times on different days at intervals ranging from 3 months to 2 years Differences were analysed by the Mann–Whitney *U* test for unpaired data.

Results

The lengths of the high pressure zone and the anal canal resting pressures and squeeze pressures are shown in *Table 1*. There was no sex difference in the median length of the pressure zone ($P > 0{\cdot}20$), whereas resting as well as squeeze pressures were significantly higher in men than in women ($P < 0{\cdot}05$).

The effect of age on the length of the high pressure zone and on resting pressure and maximal squeeze pressure was studied in subjects ≤50 years, 51–60 years and >60 years (*Table 2*) There was a trend towards decreasing values with increasing age, but no significant difference could be demonstrated. The sex difference in resting pressure and squeeze pressure was found in all age groups.

The intraindividual variation based on ten measurements performed on the same day is shown in *Table 3*. The largest individual variation in the length of the pressure zone was 10 mm, in resting pressure 26 mmHg and in squeeze pressure 68 mmHg. The median 95 per cent confidence interval for the length of the pressure zone was 4 mm, for resting pressure 15 mmHg and for squeeze pressure 48 mmHg

Table 4 shows the time-related intraindividual variation in the length of the pressure zone, resting pressure and squeeze pressure from three measurements performed over a period ranging from 3 to 24 months. The 95 per cent confidence interval

of these measurements was compared with the 95 per cent confidence interval of the measurements performed on the same day in the same subject by a Wilcoxon test; no significant difference was demonstrated, indicating that the day-to-day variation is no greater than the intraindividual variation.

Table 5 shows the result of continuous registration of spontaneous pressure changes in the anal canal during 10 min with the catheter fixed in the middle of the high pressure zone Two characteristic curves were seen· one was due to slow waves with a frequency of 0·20–0·38 and an amplitude of 6–20 mmHg, and the other to ultraslow waves (in nine of the ten subjects) with a frequency of 0·008–0·016 Hz and an amplitude of 9–24 mmHg. This variation may account for most of the observed intraindividual variation, although a certain effect of voluntary contraction cannot be ruled out.

Discussion

The accuracy of the manometric system cannot be assessed under realistic biological circumstances. Likewise it is not possible to separate the intraindividual variation studied here into 'pure' intraindividual variation and variation due to the precision (reproducibility) of the manometric system By using low compliance catheters and by withdrawing the catheters with constant speed, precision of the recording system is probably maximal, and accounts for only a fraction of the intraindividual variation found in this study.

The fact that variation between measurements in the same individual at different times was of the same magnitude as the intraindividual variation suggests that day-to-day variation is insignificant, which is an important factor in clinical practice especially when measurements are performed over a period of time to evaluate the effect of a given treatment.

The intraindividual variation in length of the high pressure zone, resting pressure and squeeze pressure was somewhat higher than that reported in a study on profilometry using microtransducers[4]; these results were, however, based on only three measurements in each subject. The results of the present study indicate that most of the intraindividual variation in anal canal pressure may be explained by slow and ultraslow waves, indicating that changes in resting anal pressure of approximately 20 per cent must be considered within the physiological range. This is true also for measurements performed at different time intervals. The amplitude of the ultraslow waves was almost the same as that of the slow waves, which is in contrast to other reports where ultraslow waves were found to have a much larger amplitude[5]. A few studies have evaluated sex differences in the length and pressure profile of the anal canal. Nivatvong *et al.*[6] studied the surgical length of the anal canal, defining it as the distance from the anal verge to the anorectal ring, measured with the right index finger; as in the present study no sex difference was found. Taylor *et al* [1] found only a slight, non-significant sex difference in anal canal pressure, whereas Read *et al.*[2], as in the present study, found a significantly higher pressure in men than in women, indicating the necessity of sex-matched control subjects. Unlike these and other investigators[2,7] we found no significant decrease in anal canal pressure with increasing age in asymptomatic subjects; it should be stressed, however, that only four subjects were >70 years old.

In conclusion, this study shows that intraindividual variation in anal canal pressure for the greater part may be explained by slow wave and ultraslow wave pressure changes normally occurring at rest, and that the day-to-day variation is within the range of these spontaneously occurring pressure variations. The importance of giving the patients some time to relax before each investigation should be stressed; this is in order to minimize the effect of voluntary contractions. Furthermore, both resting and squeeze pressures were higher in men than in women whereas no sex difference in the physiological length of the anal canal and no relationship between age and anal canal pressure was found.

Treatment of cancer of the colon: a non-specialist's point of view

A. Marston

The Middlesex Hospital, Mortimer Street,
London W1N 8AA, UK
Correspondence to: Mr A. Marston

A few months ago I operated on a man with a carcinoma of the left colon who also had three polyps in the transverse colon and the caecum, one of which was 2 cm in diameter. I carried out a subtotal colectomy and ileorectal anastomosis, a straightforward operation from which my patient made a good recovery. Examination of the specimen confirmed a Dukes' B carcinoma of the sigmoid colon, and three benign polyps. He now reports back to the outpatient department, very well, but having between two and five loose bowel motions each day.

Supposing that this patient had had the cancer but not the polyps, would there be a case for doing the same operation? After all, the entire colonic mucosa is a potential malignant field whether or not polyps are present. Consider the advantages of carrying out a sub-total colectomy and ileorectal anastomosis for every 'curable' cancer, wherever situated:

1. The operation is simple and the anastomosis is made between areas of bowel which have an abundant blood supply and which can be brought together without tension, thus minimizing the risk of anastomotic leakage, peritonitis and fistula development. No drain is needed.

2. There is a high incidence of recurrent colonic cancer following partial colectomy because of synchronous or metachronous tumours, polyps which are missed at colonoscopy or laparotomy and suture-line recurrences implanted at the time of surgery. Removal of the entire mucosal field would eliminate this problem. After all, partial cystectomy for carcinoma of the bladder is a thing of the past, and surgery for oesophageal tumours is tending more and more towards total removal of the organ, with anastomosis at a safe and accessible level.

3. Traditionally, after an operation for colonic cancer the patient is 'followed up' for 5 years, or sometimes for life. This usually means that he sees a different registrar every 6 months, who looks at the steadily thickening folder, conducts a quick physical check, and gives reassurance. Effective follow-up requires a careful examination of the colon, either by barium enema or fibreoptic colonoscopy. However if the colon has been removed, this can be achieved by a digital examination and passage of a rigid instrument, both of which are within the compass of a relatively inexperienced surgeon.

4. Colorectal surgeons have spent much time, effort and money on the detection of recurrences, and the identification of tumour markers is an expensive and cumbersome process. It remains to be seen whether a rise in carcinoembryonic antigen level above the baseline (which may or may not imply residual tumour) should lead to a further operation. The rescue rate which surgery achieves in such cases is, I suspect, exceedingly low.

Supposing we brought in a policy of subtotal colectomy and ileorectal anastomosis for every case of colonic cancer, what price would our patients pay? The function of the colon is to absorb water and its loss results in a varying degree of diarrhoea and frequency which cannot always be controlled by diet and drugs. Obviously an elderly patient with lax sphincters might be crippled by such surgery, but the life expectancy in this age group is determined by many factors other than that of colonic cancer, and common sense would indicate where the operation was inappropriate. No overall surgical policy is applicable to every patient and the procedure must be adapted to individual needs. For my own part, if I had a carcinoma of the colon, I think I would wish to have the whole organ removed and an ileosigmoid anastomosis. I would rather be loose and living than constipated and dead. Comments are awaited from colleagues in coloproctology.

Manometry is fundamental to anorectal physiology but the water-filled manometric systems commonly used have several disadvantages. To investigate the 'new' air-filled microballoon system, we compared it with a standard water-filled equivalent by measuring sphincter length, maximum resting pressure (MRP) and maximum voluntary contraction pressure (MVC) in 44 patients using the station pull-through technique. A good correlation was found for all three parameters (Spearman correlation coefficient r_S*: sphincter length = 0·86, MRP = 0·86 and MVC = 0·94,* $P < 0{\cdot}001$*). Repeat studies in 15 patients showed excellent reproducibility (*r_S*: sphincter length = 0·97, MRP = 0·96 and MVC = 0·97,* $P < 0{\cdot}001$*). Air-filled microballoon manometry gives results similar to a water-filled microballoon system and has many advantages.*

Keywords: Anorectal manometry

The most basic investigation in the field of anorectal physiology is the measurement of anal sphincter length and pressures. Most manometric systems use a pressure sensitive device in the anorectum connected to an external transducer by indistensible water-filled tubing[1–3]. The output from the transducer is then amplified and recorded on a chart recorder. Such an arrangement is prone to artefacts produced by movement of the tubing. It has to be zeroed at the anal verge and care taken to ensure that there are no air bubbles in any part of the system.

Air-filled manometry avoids these problems and, while it has been used in the past, the catheters have tended to be cumbersome, and the results have not been compared with water-filled equivalents[4–6]. This study was undertaken to determine whether an air-filled system that has been successfully used in the urogenital tract[7] was suitable for use in the anorectum.

Patients and methods

In all, 44 patients were studied, 18 men and 26 women, median age 58·5 (range 24–83) years. They consisted of 6 normal subjects, 15 patients with faecal incontinence, 7 with constipation, 3 with haemorrhoids and 13 with miscellaneous anorectal complaints. A detailed history using a standard questionnaire was obtained from each patient with special reference to anorectal complaints. This was followed by a digital examination of the rectum. No bowel preparation was used and the patients were studied in the left lateral position.

The water-filled system consisted of a 6 mm microballoon (Bristol Dippings Ltd., Bristol, UK) mounted on a ureteric catheter, external diameter 1·5 mm (*Figure 1*). This was connected to an external transducer (Statham P23Gb, Spectromed, Coventry, UK) via 1 m of indistensible tubing. The output was amplified and recorded by a multichannel pen recorder (Hewlett-Packard 7758A, Massachusetts, USA).

The balloons for the air-filled system were made by coating thin latex on a variety of stainless steel formers. A variety of shapes and sizes were tried, the final dimensions being 10 mm long and 5 mm in diameter: it was made by Dipped Latex Products, Gloucestershire, UK (*Figure 1*). It was connected via capillary tubing 30 mm long (internal diameter 0·7 mm, external diameter 2 mm) to a Druck PDCR75 transducer (Ormed Engineering, Welwyn Garden City, UK). The transducer cap was modified to reduce the 'dead' space in the system by filling it with high density plastic and drilling a hole through the centre to allow communication between the catheter and the pressure sensitive membrane of the transducer (*Figure 2*). The cap also had an 'O' ring fitted to the inside to provide an air seal. The transducer output was amplified and recorded by a Dantec 21C15 amplifier and System 2100 pen recorder (Dantec Electronics, Bristol, UK). The balloon was partially deflated when used to prevent any increase in

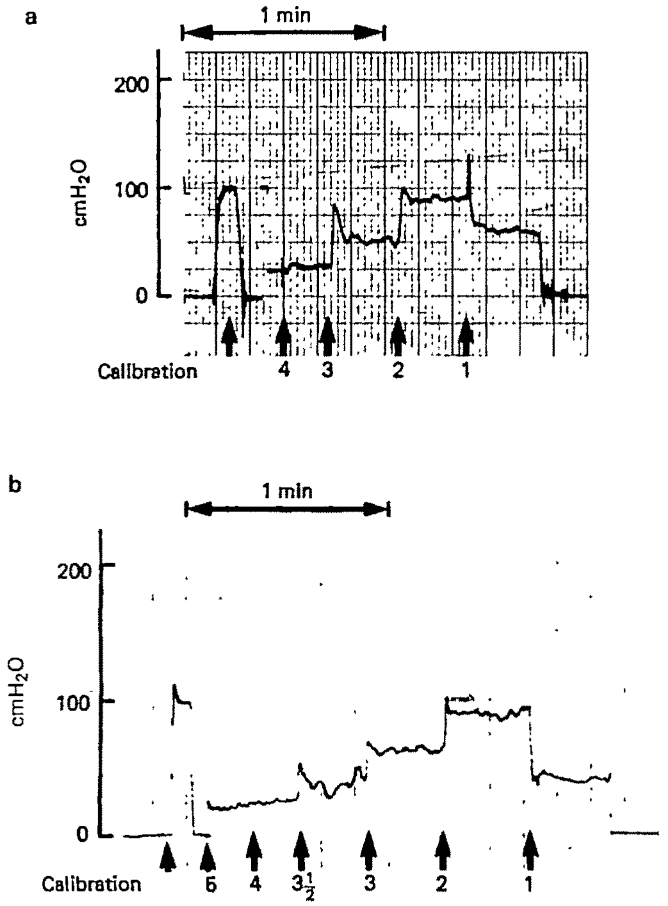

Figure 3 *Traces of resting sphincter profile from the same patient,* **a** *using water-filled and* **b** *with air-filled manometry*

pressure owing to warming of the air on insertion into the rectum. Calibration to 400 cmH$_2$O was possible using a pressurized glass container connected to a mercury sphygmomanometer The microballoon was placed in the jar with a split rubber bung round the catheter maintaining the air seal. The pressure was then increased to 100 cmH$_2$O for calibration which was performed before each study The same arrangement was also used to determine the range over which the system gave a linear response per unit rise in pressure.

The station pull-through technique was used to assess sphincter length and pressures. The catheter was inserted 7–8 cm into the rectum and a mark made at the anal verge from which all subsequent measurements were made. It was then withdrawn, initially at 0·5 cm stations until the high pressure zone was reached and the distance of this point from the verge was taken as the sphincter length. The pressure at rest was then recorded at 1 cm stations from the anal verge, the highest of which was called the 'maximum resting pressure' (MRP) (*Figure 3*). This was repeated with the patient squeezing the sphincter tight at each station to obtain the 'maximum voluntary contraction pressure' (MVC). The whole procedure was repeated on the same day in 15 patients to assess reproducibility

Statistical analysis

The correlation between techniques and reproducibility of the air manometric system were assessed using the Spearman ranked correlation coefficient. In addition, the graphical technique using the difference of the means as described by Bland and Altman[8] was also used both to compare the systems and to determine whether the two could be used interchangeably. All figures quoted are medians with the range in parentheses

Results

The air-filled system produced a linear recording of pressure up to 400 cmH$_2$O Above this an increase in pressure was recorded but with progressively smaller deflections per unit of pressure rise. The results of sphincter length, MRP and MVC for the water-filled manometry were 3·5 cm (2–4·5), 85 cmH$_2$O (25–220) and 180 cmH$_2$O (55–560) while those from the air-filled system were 4 cm (2–5), 70 cmH$_2$O (15–170) and 170 cmH$_2$O (65–460) respectively. The Spearman correlation coefficient between these techniques for sphincter length, MRP and MVC was 0·86, 0·86 and 0·94 respectively ($P < 0{\cdot}001$) (*Figure 4a, b* and *c*). Using the difference of the means method it was evident that the two systems were not interchangeable as the value for two standard deviations (2 s.d.) of sphincter length, MRP and MVC were 0·72 cm, 40 cmH$_2$O and 85 cmH$_2$O respectively (*Figure 5a, b* and *c*).

Reproducibility using the air system as assessed by the Spearman correlation coefficient was excellent, being $> 0{\cdot}96$ for each parameter ($P < 0{\cdot}001$). This was also the case using the difference of the means method where 2 s.d. for sphincter length, MRP and MVC were 0, 10 and 20 cmH$_2$O respectively.

Discussion

There are many available methods for measuring anorectal pressure which make comparison between centres difficult, and which occasionally produce conflicting results[1–6,9–12]. Water-filled systems are most commonly in use, either employing perfused catheters or microballoons as used in this study. Each has its own particular advantages and disadvantages and none appears to be accepted as the 'gold standard'. Perfusion manometry measures 'yield' pressures[13] and requires rather bulky equipment but it is relatively easy to make multilumen

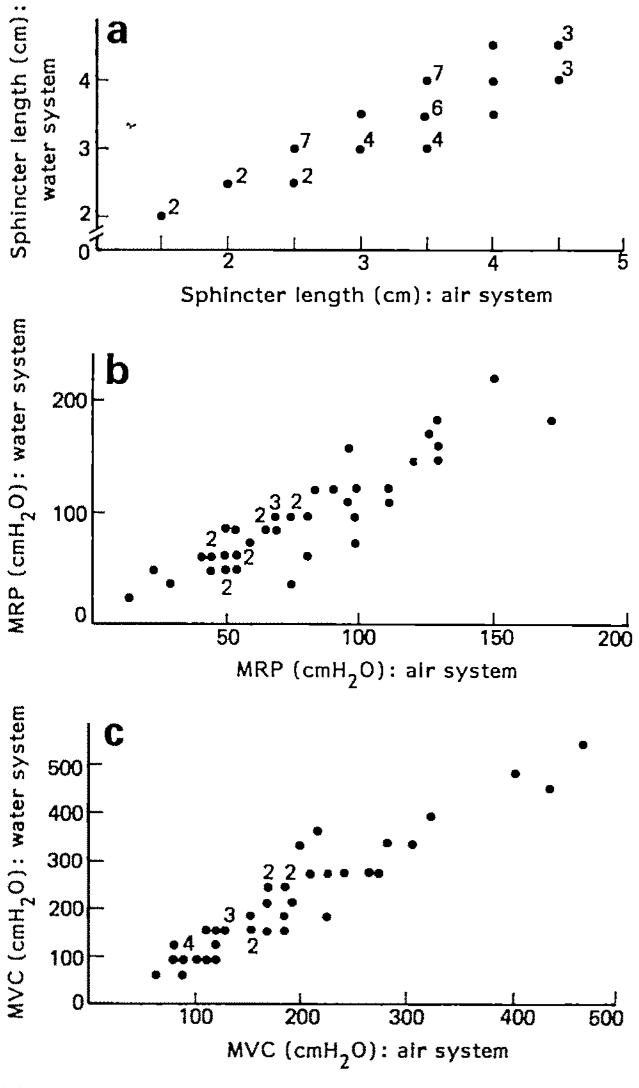

Figure 4 *Spearman ranked correlation of* **a** *sphincter length,* **b** *MRP and* **c** *MVC using the two systems. MRP, maximum resting pressure, MVC, maximum voluntary contraction pressure,* $r_s = 0{\cdot}86$, *0 86 and 0 94 respectively,* $P < 0\ 001$ *for each correlation*

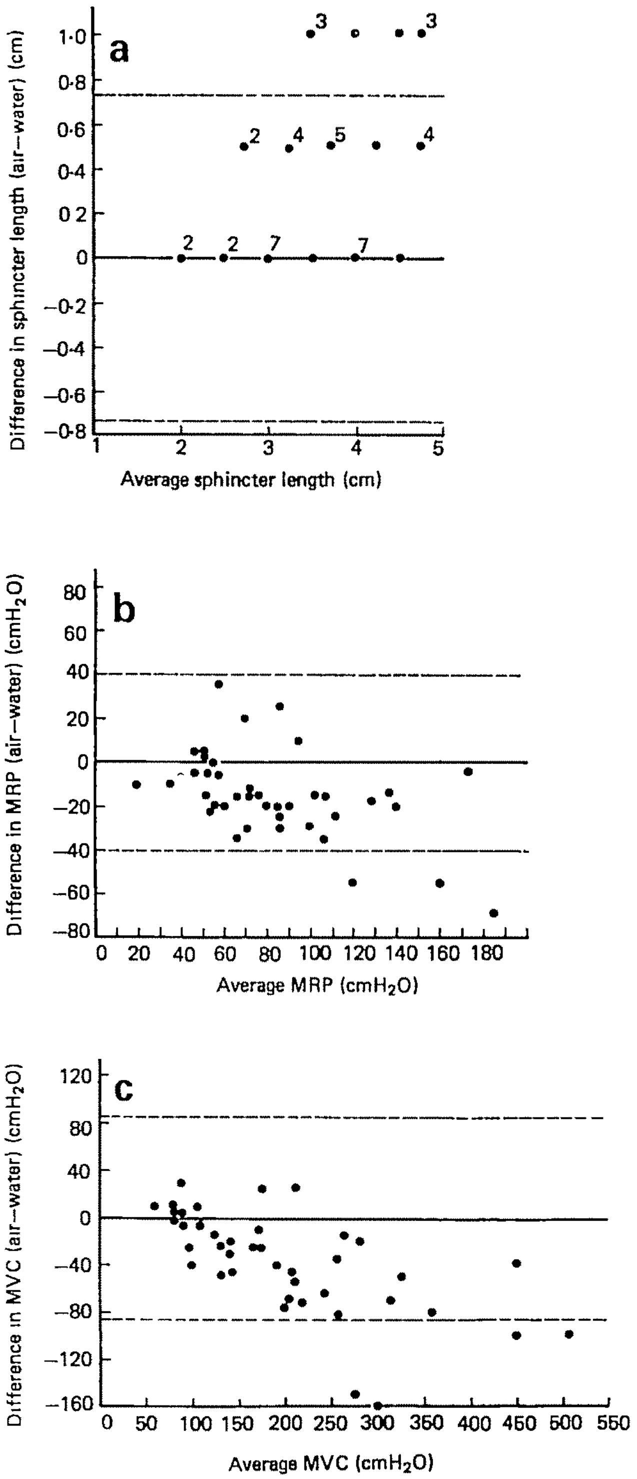

Figure 5 *Correlation of water- versus air-filled manometry using differences of the mean* **a** *sphincter length* **b** *MRP and* **c** *MVC. The sphincter length was in general longer when measured with the air-filled system Using this analysis it is evident that the degree of correlation does not permit the interchangeable use of the two systems. catheters for measuring pressures from several discrete points in the gut[1]. Microballoon assemblies tend to be larger in diameter and as the sphincter responds to distension by contracting they record higher pressures[14,15]. Both must be free from air bubbles, are very prone to artefacts due to movement of the connecting tubing and have to be zeroed at the anal verge before each study. For these reasons they would be entirely unsuited to, for example, manometry in conjunction with radiological studies or with ambulatory subjects[16]

The more recent advent of microtransducer catheters has provided an alternative to using an external transducer[10] They have the advantage of simplicity in use and, being of narrow diameter, they minimize disturbance to the sphincter. We have compared these catheters using the station pull-through technique with water-filled microballoons and have shown their limitations due to the directional nature of the sensing membrane and radial variation in anal canal pressure[17]. Furthermore, these catheters are much more expensive than those employing an external transducer

Any new system, therefore, must possess definite advantages over those currently available. We believe that, at the risk of further confusion to the literature, air-filled manometry is a good alternative. The pressures correlate well with water-filled manometry, and it is simple to set up as any conventional external transducer can be modified to take the air catheter. These modifications are designed to reduce the dead space between the microballoon and the transducer so that pressure changes are transmitted directly to its sensitive membrane. The catheters themselves are easy to construct and use and precautions to exclude air bubbles are obviously unnecessary. Zeroing is achieved simply by pressing the appropriate button on the amplifier and is independent of the height of the catheter or transducer. Furthermore, they are free from any artefact due to movement of the catheter or its connecting tubing. If required, multilumen catheters can be constructed using lengths of capillary tubing protected by an outer catheter.

The sphincter length was longer using the air system than that recorded using water-filled balloons but this is to be expected as the balloon itself was 1 cm long. The advantage of a longer balloon however outweighs this problem, which could be corrected for in use. The longer balloon results in an average pressure from a zone of the anal canal to be recorded, thereby minimizing error due to radial and longitudinal variation in anal canal pressure[18] to which side hole perfused systems and microtransducer catheters are prone[17].

The sphincter pressures were in general lower when recorded by the air system. This is probably due to the smaller diameter balloon used in the air-filled system. It is unlikely that these differences in pressure were owing to the differences in the transducers, amplifiers and pen recorders used as both systems had similar filter settings and recorded linear increases in pressure up to 400 cmH_2O The differences between the recorded pressures, however, did mean that the two systems could not be interchanged, and therefore any longitudinal study would require the exclusive use of one or other technique.

Air balloons do require the transducer to be reasonably close to the patient as long lengths of connecting tubing increase the dead space and therefore reduce the range over which the system gives linear results for a given pressure change In our unit the transducers are not fixed in any way and lie on the bed during the studies. In situations where the patient is more mobile, for example if manometry is combined with radiology, they can easily be attached to the patient's waist.

In conclusion, air-filled microballoon manometry offers many advantages over water-filled systems for routine anorectal investigation and is inexpensive and easy to use.

Case report

A 57-year-old nursing auxiliary presented in October 1986 with a 5-month history of passing up to 10 watery stools daily. After barium enema a diagnosis of irritable bowel syndrome was made and treatment with mebeverine hydrochloride temporarily relieved the symptoms In June 1987 the patient was admitted urgently with acute abdominal pain and vomiting. Her bowel frequency had increased to 15–20 stools daily Air-fluid levels were present on a plain abdominal film and symptoms failed to settle with conservative treatment.

At laparotomy a penetrating transmural jejunal ulcer was present 6 cm from the duodenojejunal flexure There was a 10 cm mass in the head of the pancreas and transduodenal Trucut biopsy revealed acute pancreatitis A diagnosis of gastrinoma in the head of the pancreas causing small duct obstruction and resulting in localized pancreatitis and jejunal ulceration was made The ulcer was oversewn and the abdomen closed Postoperative serum gastrin was 377 µmol/100 ml (reference range 10–30). Initial treatment with ranitidine (300 mg t.d s.) did not control diarrhoea and only partially resolved dyspeptic symptoms. Gastroscopy revealed massive post-bulbar ulceration as far as the endoscope would reach. Acid output studies showed a basal acid secretion of 27 mmol/h (normal range 0–6), and a maximal acid output of 110 (normal range 8–40). Pituitary fossa X-rays (to exclude multiple endocrine neoplasia syndrome) were normal Ultrasound scan of liver, computed tomography scan of liver and pancreas, and endoscopic retrograde cholangiopancreatography were normal Coeliac axis arteriogram showed a blush between the posterosuperior and anterosuperior pancreaticoduodenal arteries with early filling of an adjacent enlarged vein suggestive of tumour circulation.

One month before planned definitive surgery treatment was begun with octreotide 50 µg b d (subcutaneously) and within hours there was complete symptomatic relief. Serum gastrin levels were reduced (*Figure 1*) and basal acid output fell to 2·8 mmol/h. Repeat gastroscopy after 3 weeks therapy showed complete healing of jejunal ulceration

At the second laparotomy pancreaticoduodenectomy was performed with a separate Roux loop for the pancreatic anastomosis[1] (*Figure 2*). Serum gastrin measured 2 days after surgery was 22 µmol/100 ml (*Figure 1*). Histological examination of the resected specimen showed a completely resected islet cell tumour in the head of the pancreas with nodal metastases Postoperative recovery was uneventful At recent follow-up the patient is asymptomatic, takes no drug therapy and serum gastrin levels are within the normal range

Discussion

The surgical treatment of patients with non-metastatic gastrinoma is controversial. In some centres the preferred treatment is total gastrectomy combined with enucleation of easily accessible primary tumours[2–4]. The only patients cured in this way are those in whom a solitary tumour has been completely enucleated or in whom a duodenal wall tumour has

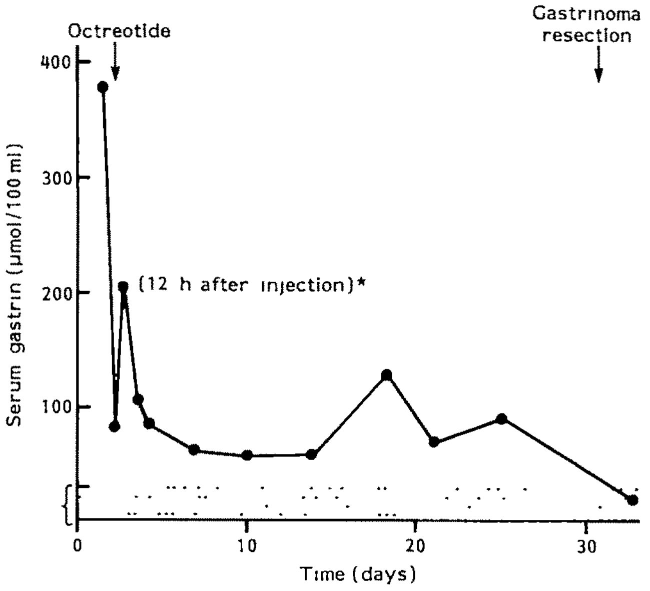

Figure 1 *Serial pre-operative and postoperative gastrin levels Treatment began with octreotide, given at a dosage of 50 µg b.d subcutaneously *All other serum measurements were taken within 4–6 h of octreotide injection*

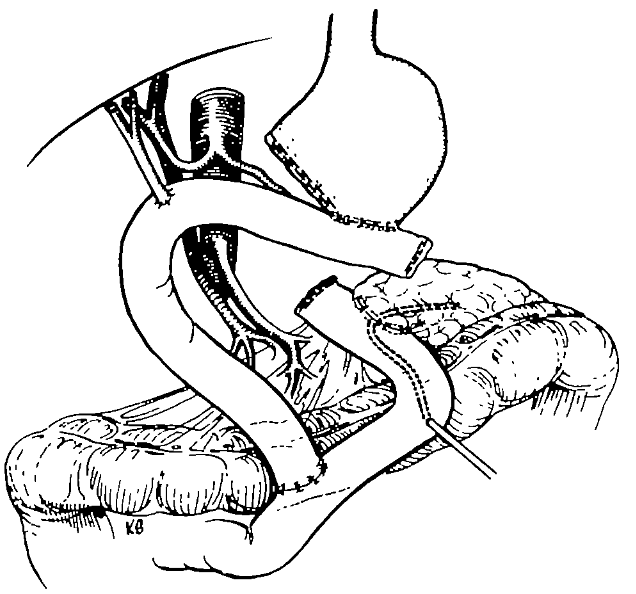

Figure 2 *Method of anastomotic reconstruction after Whipple-type resection*[1]

been incidentally removed with the gastrectomy specimen. Cure, defined as a decrease in the gastrin levels to the normal range within 48 h of surgery, occurs in approximately 15 per cent of patients and the 10-year life-table survival rate is 50 per cent[5]. A more radical approach involving pre-operative imaging techniques with ultrasound and CT scanning combined with portal venous sampling to localize pancreatic primary tumours can increase the resectability rate[6]. In experienced hands with this approach the cure rate can increase to between 20 and 30 per cent with no operative mortality[6,7]. We adopted this latter approach with a view to curative resection and since octreotide can ameliorate experimentally induced acute pancreatitis[8], we hoped that the localized pancreatitis in our patient would resolve.

Ellison and colleagues have recently reported 10 patients with the Zollinger–Ellison syndrome treated with subcutaneous octreotide[9]. Serum gastrin levels were reduced and gastric acid secretion was almost completely inhibited for 18 h after a single 100 μg subcutaneous injection. Similar reductions in serum gastrin and acid secretion were achieved in our patient with complete symptomatic relief. Pre-operative treatment with octreotide requires further evaluation in the management of patients with Zollinger–Ellison syndrome suitable for surgical resection.

Experience of restorative proctocolectomy with ileal reservoir

W. G. Everett

Addenbrooke's Hospital, Hills Road, Cambridge, CB2 2QQ, UK

Correspondence to:
Mr W. G. Everett

The experience gained with restorative proctocolectomy and ileal reservoir in 60 patients is presented. Fifty-two patients had W reservoirs and the operative technique of the procedure is described in detail. Forty patients had a defunctioning ileostomy and 20 had a single stage procedure. There was no perioperative mortality. The main complications were sepsis (28 per cent), intestinal obstruction (18 per cent) and reservoir ileitis (20 per cent). There was a significant improvement in sepsis rate (from 20 to 4 per cent) and hospital stay (from 31·8 to 15·6 days) with increased experience. The functional results of 48 patients with W reservoirs was assessed. The mean number of evacuations per 24 h (±s.d.) was 3·8 ± 0·2. Sixty-five per cent of patients did not evacuate at all, or rarely, at night and none evacuated more than once at night. Forty-four per cent of patients took antidiarrhoeal agents. Continence was normal in 50 per cent of patients. Minor leakage occurred in 46 per cent of cases, frequent leakage in 4 per cent and incontinence in none. Sexual function in 29 men was normal. Ninety-four per cent of patients considered the result of their operation to be good or excellent.

Keywords: Restorative proctocolectomy, ulcerative colitis, familial adenomatous polyposis

The first restorative proctocolectomy with ileal reservoir was performed by Sir Alan Parks in 1976 and a report of five cases was published 2 years later[1]. Although several hundreds of these operations have been carried out in the USA[2–4], the experience in this country has been much smaller and even in some large centres the operation is not performed. As the number of publications from the UK is small there is a need for more data and the results from one unit in Cambridge are therefore reported.

Parks *et al.* in their original description of the operation used a three-loop S reservoir but it was found that only half the patients could void spontaneously, the remainder needing to use a catheter[5]. It was subsequently shown that the problem in emptying was related to the length of the distal ileal segment[6] and if this was kept short this difficulty was largely overcome[7]. Evacuation occurs spontaneously with a two-loop J reservoir as this provides dependent emptying and completely avoids the distal ileal segment[8]. This type of reservoir is however associated with increased frequency of emptying which is probably the result of a smaller capacity. With a view to overcoming this problem Nicholls designed a four-loop W reservoir with a greater capacity and no distal ileal segment[9]. In 1984 the author, independently of Nicholls and Lubowski, designed a very similar four-loop reservoir. The operative technique is presented together with the complete experience of restorative proctocolectomy in one centre.

Patients and methods

Patients

Between December 1979 and February 1988, 60 restorative proctocolectomies were performed. The first six were S reservoirs, there was then one J reservoir and the remaining 53 were W reservoirs. There were 33 men and 27 women operated on (male:female ratio, 1·2:1). Ages ranged from 18 to 65 years (mean age 33·9 years). Four patients were over the age of 50 years.

Fifty patients had inflammatory bowel disease, of whom two were subsequently found to have Crohn's disease in spite of the most careful preoperative review of the pathology, radiology and clinical course. Ten patients had familial adenomatous polyposis. In four cases there was an associated large bowel carcinoma: two with ulcerative colitis had neoplasms of the caecum and upper rectum and two with familial adenomatous polyposis had splenic flexure and sigmoid growths.

Methods

Preoperative preparation. The patient is put on a fluid diet for 24 h before operation to ensure that the small bowel contains no food matter. If a colectomy has not previously been performed the bowel is prepared with sodium picosulphate (Picolax®, Nordic Pharmaceuticals Ltd., UK). If a colectomy has already been carried out the rectal stump is washed out.

The abdominal dissection. The patient is catheterized and placed in the Lloyd-Davis position. The abdomen is opened through a long left paramedian incision.

The dissection is begun by incising the peritoneal reflection on the left of the sigmoid mesentery. The ureter is identified and pushed posteriorly. The peritoneum on the right aspect of the mesosigmoid is then incised and the distal part of the vascular pedicle containing the inferior mesenteric vessels is ligated in continuity and divided. The mesosigmoid is then lifted forwards off the aorta and the dissection carried downwards into the pelvis keeping close to the mesentery. The hypogastric nerves are then clearly seen as two strands lying posteriorly beneath the pelvic fascia at the level of and inferior to the lumbosacral disc. (Their preservation is of great importance in male patients.) The pelvic peritoneum is then divided on either side of the rectum and across the midline as low as possible. The dissection is continued posteriorly between the mesorectum and the presacral fascia. This plane is clearly defined and the pelvic fascia should not be breached. Scissor dissection is used throughout and blunt dissection with a swab on a holder is avoided as this may damage the pelvic nerves. The lateral ligaments are then divided as close as possible to the rectal wall. The rectum is now fully mobilized and a Hayes' clamp is placed across the bowel just above the intended site of division. An assistant then washes out the rectal stump with water until it is completely clean. A sigmoidoscope is inserted so that any fluid can be sucked out and the distance of the clamp from the anal verge measured. The aim is to divide the rectum 7–8 cm above the anal margin. This is done with diathermy, taking care to coagulate any blood vessels so that following removal of the rectum the pelvis is absolutely dry.

The colectomy then proceeds in the standard manner with preservation of the omentum. The terminal ileum is transected obliquely

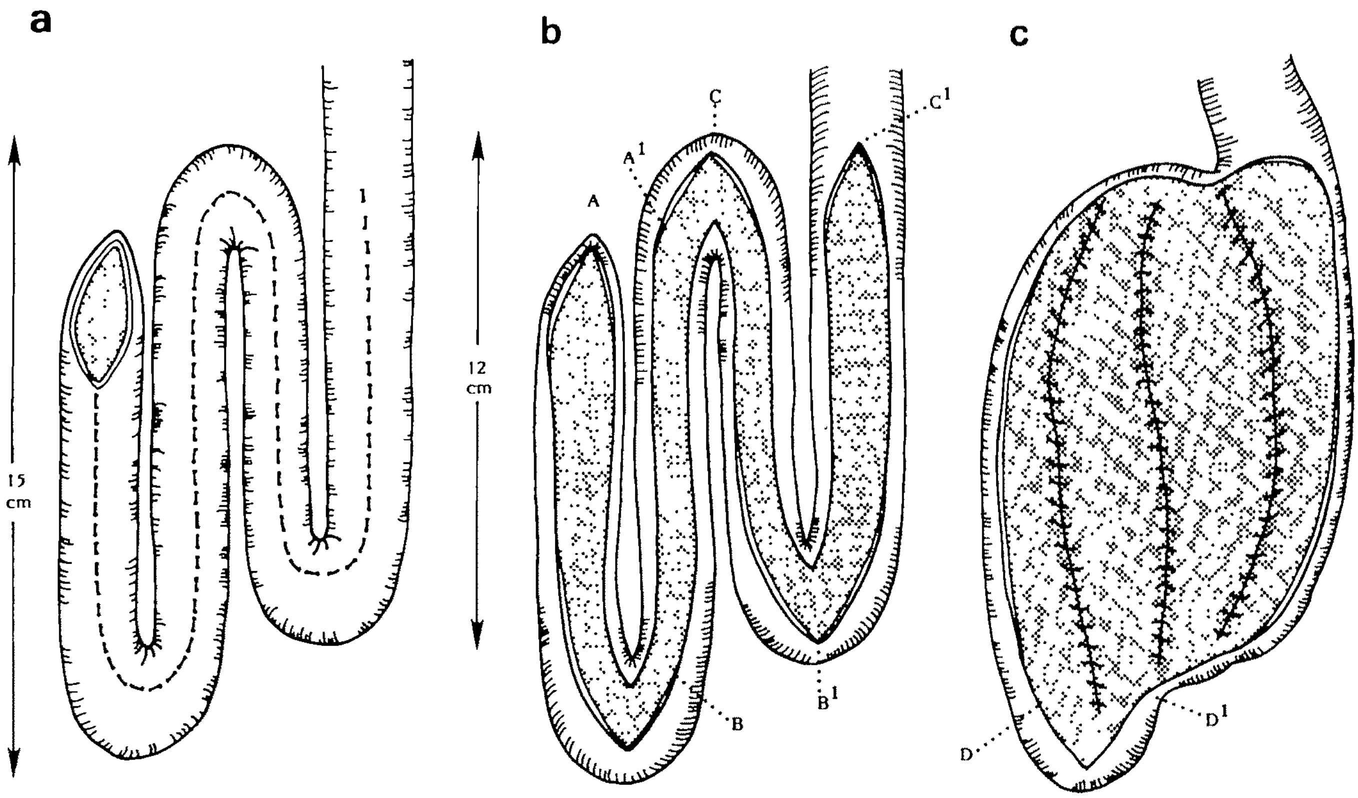

Figure 1 a *The terminal ileum laid out with the cut distal end on the patient's right showing the line of incision on the antimesenteric border of the bowel,* b *the bowel after it has been opened: A is joined to A^1, B to B^1 and C to C^1,* c *the three completed posterior suture lines: D is joined to D^1*

just proximal to the ileocaecal junction and the specimen removed. At this stage the vessels of the small bowel mesentery are inspected. The terminal ileum must come down into the pelvis without tension and, to obtain increased length, the ileocolic artery and, if necessary, some of the arcade vessels of the superior mesenteric artery are divided. The base of the mesentery may also require mobilization by dissection of the main vascular pedicle off the posterior abdominal wall and duodenum When fully mobilized the terminal ileum should extend several centimetres below the symphysis pubis.

Mucosal proctectomy A Parks' retractor is inserted into the anus and the submucosa injected with 1/300000 adrenaline solution. The mucosa is divided just above the dentate line and, with scissors, dissected off the underlying muscularis propria in four strips. Care is taken not to damage the muscle in stripping the mucosa or by excessive use of diathermy

Construction of the reservoir (Figures 1–3) The terminal ileum is laid out as four loops with the obliquely cut distal end lying on the patient's right (*Figure 1a*) Each of the four limbs, which measure approximately 12, 12, 15 and 12 cm in length (from proximal to distal), is held with Babcock forceps A seromuscular stay suture is inserted at the inner aspect of each of the three bends and these are used at the completion of the reservoir to inspect the posterior suture lines The bowel is then incised along the antimesenteric border (*Figure 1b*) and the cut edges approximated with a continuous all-layer suture of 3/0 Polyglyconate (Maxon®, Davis and Geck, UK) The stitching of the three posterior suture lines is done from the mucosal surface of the bowel (*Figure 1c*). The outlet of the reservoir is then constructed by approximating the inferior portions of the posterior wall (*Figure 2*). This needs to be sufficiently large to admit the blades of the Parks' retractor when the ileoanal anastomosis is performed and should normally admit two fingers. A mucosa burying stitch is used to construct the anterior suture line This begins inferiorly at the outlet of the reservoir and is continued proximally to the inlet, which should have a wide oblique opening. The suture line is carefully inspected The points where two suture lines meet are reinforced as are any places where there is a gap between stitches The capacity of the reservoir is then measured, using a bladder syringe, and its watertightness is tested The capacity usually ranges from 150 to 300 ml Two lateral stay sutures are placed at the outlet of the reservoir to guide it into the pelvis

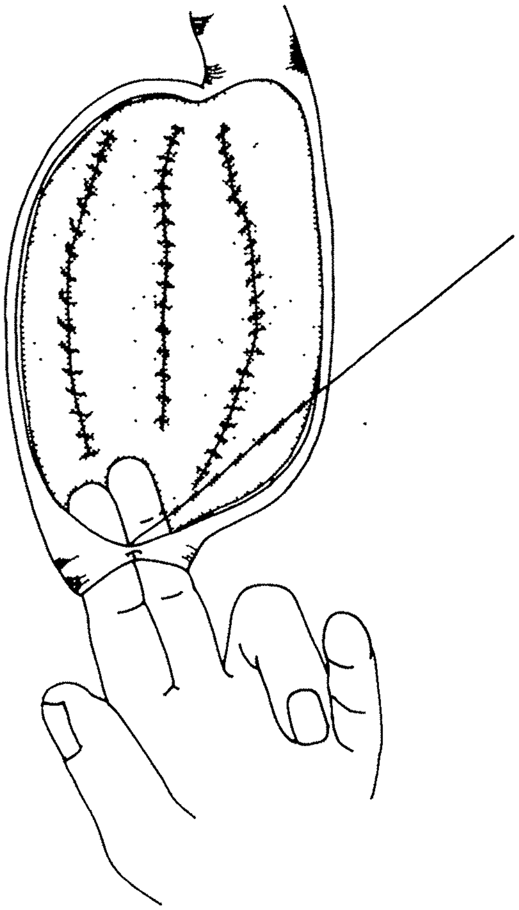

Figure 2 *Construction of the outlet of the reservoir which should admit two fingers*

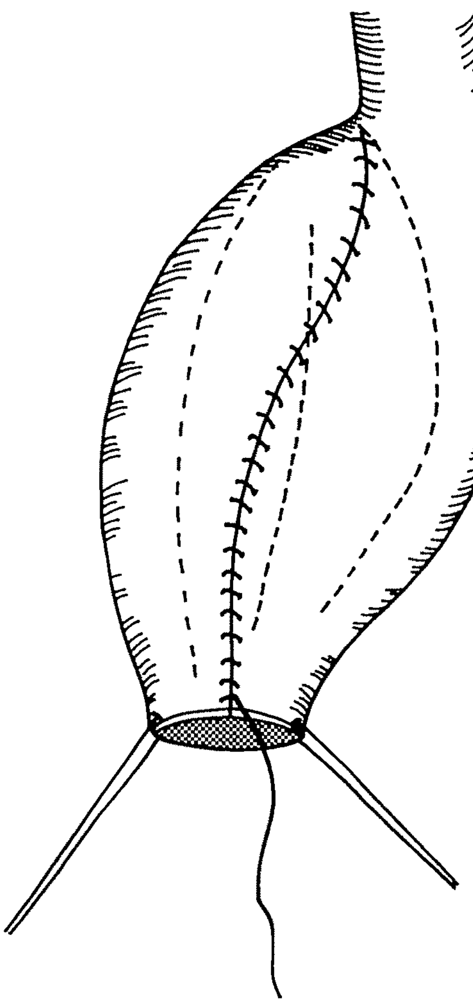

Figure 3 *The completed reservoir showing the anterior suture line with the anterior suture line stitch left long to orientate the pouch, and two lateral stay sutures to guide the reservoir into the pelvis*

(*Figure 3*) and the cut end of the anterior suture is left long to aid in its orientation.

Ileoanal anastomosis A Parks' retractor is used with shortened blades which enables the reservoir to be passed through the opened blades into the anal canal by applying traction on the lateral stay sutures. The anterior suture line stitch of the reservoir is then picked up with a haemostat. The ileoanal anastomosis is constructed with interrupted stitches using 2/0 polyglactin (Vicryl®), on a J needle (Ethicon Ltd., UK) which can be readily manipulated in a confined space. A stitch is first placed on either side of the anterior suture of the reservoir and one stitch is placed posteriorly. The Parks' retractor is then removed and holding the lateral stay sutures the blades are reinserted into the pouch. A stitch is placed at 90° and 270° and then each quadrant sutured in turn with another three or four stitches With each stitch the needle first picks up the free edge of the opening of the reservoir and then a small bite of the internal sphincter half way up the anal canal emerging at the cut edge of the mucosa. When the stitches are tied the suture line is pulled upwards and comes to lie in the midanal canal Care is taken not to take deep bites of the anal canal anteriorly where, in women, a fistula between the reservoir or anal canal and the vagina may result. Two Redivac® (O.E.C Orthopaedic) drains are passed between the posterior aspect of the reservoir and the anal canal and brought out through the abdominal wall. Finally a Medina® (Astra Meditec, UK) catheter is guided into the reservoir by the abdominal operator and sutured to the buttock with a nylon stitch

A temporary defunctioning loop ileostomy was fashioned in 40 patients, in the remaining 20 this was omitted

Postoperative management Gentamicin 80 mg and metronidazole 500 mg IV are given at the start of the operation and continued 8-hourly for 4 days. The Medina catheter is removed on the 5th or 6th day, or earlier if it becomes blocked, and the urinary catheter removed at the same time.

Patients who have had a defunctioning ileostomy performed are reviewed in the outpatient department at 1 month Digital examination, sigmoidoscopy and X-ray examination of the reservoir are carried out and if these are satisfactory the ileostomy closed

Follow-up. Patients were seen regularly at 3–6-month intervals by the author The mean follow-up was 29·6 months In addition all patients completed a detailed questionnaire.

Results

Complications

There were no perioperative deaths. One patient died of amyloid disease 7 years after surgery but this was present at the time of operation.

The postoperative complications following restorative proctocolectomy are shown in *Table 1*. The late complications are shown in *Table 2*.

The most significant postoperative complication was sepsis, occurring in 18 per cent of patients. A further six patients developed late perineal infection bringing the total incidence up to 28 per cent. Septic complications occurred mainly early in the series. Comparing the first 30 cases with the second 30 cases, the postoperative sepsis rate fell from 20 to 4 per cent and the total sepsis rate from 37 to 23 per cent. In five cases surgical intervention was necessary to deal with these complications.

Intestinal obstruction was also common (overall incidence 18 per cent). It occurred six times in the immediate postoperative period and all resolved spontaneously. Laparotomy was required in four of five late obstructions.

Reservoir ileitis was equally common (20 per cent). The diagnosis was made mainly on sigmoidoscopic appearance and

confirmed by biopsy in most cases. In one instance, the symptoms were sufficiently bad to necessitate removal of the reservoir. Four additional patients required hospital admission to treat diarrhoea and electrolyte imbalance, whilst in eight the symptoms were less severe. Metronidazole or Augmentin (Beecham, UK) controlled symptoms in all but one case but many patients remained on a small dose of antibiotics for several months.

Stricturing of the ileoanal anastomosis occurred in three patients (5 per cent). In two cases this was minor. In one case, this was more severe and resulted from pelvic sepsis. All responded to digital dilatation.

In four cases (7 per cent) it was necessary to remove the reservoir and re-establish a permanent ileostomy. In two patients this was due to technical failure occurring early in the series: one as a result of anastomotic dehiscence and one from recurring 'pouchitis' due to impaired emptying. In the other two cases the reservoir was removed after some years: one because of Crohn's disease and the other because of bleeding from amyloid disease.

The most objective assessment of the incidence and severity of postoperative complications is by measurement of hospital stay. Comparison of the first 25 with the last 25 cases showed a highly significant difference in hospital stay between the two groups (mean 31·8 days, range 12–124, s.d. 26·0 compared with a mean of 15·6 days, range 8–34, s.d. 7·0; $t = 2·977$, d.f. 48: $P < 0·005$). Three serious complications occurring early in the series were largely responsible for this difference.

Although the majority of patients ($n = 40$) had a defunctioning ileostomy and therefore underwent a two-stage procedure, 20 patients had a single-stage procedure without ileostomy (15 for ulcerative colitis, five for familial adenomatous polyposis). The length of hospital stay in 37 patients in whom the ileostomy had been closed was compared with that in the 20 patients who underwent restorative proctocolectomy without an ileostomy. The results of the two groups are given in *Table 3*. Four patients in the single-stage group developed complications and in two this necessitated establishing an ileostomy. The majority however did well and overall a significant reduction in hospital stay was achieved by a one-stage procedure.

Function

Only one patient with an S reservoir had to use a catheter for evacuation. One patient with a W reservoir preferred to use a catheter intermittently to relieve tenesmus although he can evacuate normally.

The functional results for 48 W reservoirs are given in *Table 4*. These results do not differ significantly from the series as a whole except that one patient with an S reservoir was incontinent.

Of the patients that had to evacuate at night only one-third found it necessary to take antidiarrhoeal agents. Minor impairment of continence resulted in occasional soiling or a mucous leak at night but not sufficient to cause soreness or necessitate wearing a pad.

Sexual function was normal in all 29 men who were questioned and there were no cases of impotence or retrograde ejaculation. Two of the women became pregnant and had normal vaginal deliveries.

Patients were asked to assess the result of their operation as excellent, good, satisfactory or bad and the conclusions are given in *Table 5*. There were two failures occurring early in the series where the reservoir had to be removed. Two further patients who had satisfactory results at the time of completing the questionnaire subsequently went on to have their reservoirs removed, one because of Crohn's disease and the other because of bleeding from amyloid disease. Ninety-eight per cent of patients with W reservoirs and 96 per cent of the series as a whole were well satisfied with the result of their surgery.

Discussion

Restorative proctocolectomy is a relatively safe procedure with low operative mortality. In 596 patients collected from various sources the mortality rate was only 0·3 per cent[10]. The morbidity was however considerable. There are two major postoperative complications: sepsis and intestinal obstruction.

A high incidence of infective complications has been reported by most authors, but this decreases with experience. This was certainly the case in this series where the postoperative sepsis rate fell from 20 to 4 per cent. Pelvic sepsis is the major problem[10] and is often the result of dehiscence of the ileoanal suture line. Sepsis can be prevented by avoiding contamination by washing out the rectum before its division, avoiding pelvic haematoma by meticulous haemostasis when the rectum is divided and by accurate suturing of the ileoanal anastomosis. The latter is the most difficult part of the operation but is greatly facilitated by placing the blades of the Parks' retractor within the pouch and the use of an atraumatic suture on a J needle.

The length of the anorectum that is left seems to be of little importance from a functional point of view[7] and there appears to be no harm in dividing the bowel as low as the anorectal junction. Division of the rectum too high simply makes the procedure more difficult. The removal of the additional mucosa may result in haematoma and the cuff of rectum may obstruct the pouch being brought down into the anal canal.

In the construction of the reservoir there are two ideals. Firstly, catheterization of the pouch should not be necessary

Table 4 *Functional results in 48 W reservoirs*

and secondly the number of evacuations should be reduced to a minimum. The fact that catheterization was necessary in almost 50 per cent of S pouches was shown to be due to the long distal ileal segment[6] and, if this was shortened, Dozois *et al.*[7] felt that the problem could be eliminated. Even if this is the case, the S pouch suffers from the disadvantage that the opening can only be made as wide as the ileum. For accurate ileoanal anastomosis the author believes it is essential to place the blades of the Parks' retractor within the reservoir; in some instances the terminal ileum is too narrow for this to be possible. The surgeon therefore has the choice of a J or W reservoir. Nicholls[3] believes that the frequency of evacuation is inversely related to the capacity of the reservoir. He found that J pouches had a mean capacity of only 172 ml whereas W pouches had a mean of 325 ml. The corresponding frequency of evacuation was 5·5 and 4·1 per 24 h respectively. In a larger series Nicholls and Lubowski[9] report a frequency of 3·3 which compares favourably with 3·8 in this series. It can be argued that it should be possible to construct a J reservoir of equal capacity by making the two limbs sufficiently long. However no one has so far reported a series of J pouches where the mean frequency of evacuation has been less than 5 times per 24 hours.

The construction of a W pouch is no more difficult than a J pouch The ideal capacity for a reservoir has not yet been determined but it would be relatively easy to increase this. A very large reservoir may however fail to empty adequately The capacitance, or ability of the reservoir to stretch, may also be of importance and this could be less with a double-layer suture technique The author has used a single layer of continuous 3/0 polyglyconate. This has been satisfactory in every instance where a defunctioning ileostomy has been performed, and barium examination has failed to show any leakage. In two cases, however, leakage occurred from reservoirs that had not been defunctioned. A single-layer technique therefore may not be ideal.

The avoidance of a defunctioning ileostomy is controversial. It should certainly be performed in every case until the surgeon is confident about performing the ileoanal anastomosis. If this is entirely satisfactory without tension, with a good blood supply, accurate suturing and the patient not on high dose steroids, then it is probably safe to omit an ileostomy. It would probably be safest, however, to drain the reservoir with a Medina catheter for 7 days postoperatively because the strength of anastomoses is very small up until this time[12].

Avoiding an ileostomy has obvious attractions in decreasing the number of operative procedures and the hospital stay. Loop ileostomies are often difficult to manage and may result in additional admissions because of ileostomy diarrhoea, skin excoriation or obstructive episodes.

The overall results of restorative proctocolectomy compare favourably with those of proctocolectomy and ileostomy The subjective assessment shows that 95 per cent are well satisfied with the procedure Frequency of evacuation is usually well tolerated because of the absence of urgency and the fact that the patient can delay defaecation until it is convenient. Night evacuation is a minor problem with the W pouch[9]. Although Nicholls and Lubowski found that in 92 per cent of their patients continence was normal, this was not the case in this series. In almost one-half of the patients there was a minor impairment of continence resulting in occasional leakage on exertion or a mucous leak at night. This, however, was of little inconvenience to the patient and neither necessitated wearing a pad, nor taking antidiarrhoeal drugs. The difference in the results of the two series is probably related to the method of assessment Nicholls and Lubowski[9] give figures for 'normal' continence and faecal leakage but it seems likely that there is a group between these two where continence is not entirely normal

In this series a simple preoperative assessment of sphincter tone was made by digital examination, and physiological tests of sphincter function were not performed In the two patients that had frequent leakage following surgery, one appeared to develop sphincter impairment after a protracted illness, the other had good sphincter tone with severe reservoir ileitis. Preoperative tests of sphincter function might have identified the former but on the whole it was felt that they would have contributed little.

The preservation of normal sexual function is of the utmost importance in treating such a young age group and it is encouraging that there have been few reports of impotence following restorative proctocolectomy. It is, however, disturbing that Dozois[11] reports a 9 per cent incidence of retrograde ejaculation owing to damage of the hypogastric nerves. Nicholls and Lubowski[9], who make a point of keeping the plane of dissection close to the rectum, have had no cases of retrograde ejaculation. Damage to the hypogastric nerves may occur in the lumbosacral region and it may be equally important to lift the mesorectum off the posterior abdominal wall at this point where the hypogastric nerves should be clearly seen and traced into the pelvis. The author has had no instances of retrograde ejaculation in 29 men he has operated on and believes that visualization of these nerves is as important to their preservation as it is, for example, in avoiding damage to the recurrent laryngeal nerves at thyroidectomy. The most significant problem in the long term has been reservoir ileitis which in this series has occurred at some stage in 27 per cent of patients, and often required long term antibiotics. Further research into the aetiology and treatment of this condition is required.

The incidence of complications following restorative proctocolectomy and ileal reservoir, when performed by surgeons who have gained experience of the procedure, is acceptable In the opinion of the author, this operation is the procedure of choice and should be offered to the majority of young people with ulcerative colitis or familial adenomatous polyposis. However, it is recommended that the operation should be performed in a few centres where surgeons can gain sufficient experience to obtain good results.

Computer-aided diagnosis: a review

G. C. Sutton

Dr G. C. Sutton

Fifteen years ago, computer-aided diagnosis of the acute abdomen promised much. Today it is little used. Studies have been flawed by poor trial design, bias, selective reporting of results, statistical naivety and spurious conclusions. The computer system lacks 'common sense' and is less accurate than clinicians. Yet its introduction has been associated with improved patient management and outcome. Much of the effect arises from structured data collection methods and some from audit feedback to clinicians. It is on these innovations, not on the computer, that future work should focus.

Keywords: Computer-assisted diagnosis, acute abdomen

In 1972, de Dombal and co-workers in Leeds described a system for computer-aided diagnosis of the acute abdomen. Results[1,2] were spectacular: the computer had a diagnostic accuracy exceeding that of a consultant surgeon, and there were improved rates for negative laparotomy and perforated appendix. Over 15 years on, computers are common in the National Health Service, UK, yet their impact on clinical decision making is muted. Whatever happened to this promising development?

The literature of computer-aided diagnosis is extensive but much is theoretical or speculative, the present review considers only the practical effectiveness of computer-aided diagnosis and is restricted to published scientific accounts. It focuses on the acute abdomen as this is a clinically important, well-documented test area for computer diagnosis There are relatively few diseases to consider. Correct diagnosis should lead promptly to correct management decisions and improved patient outcome; unaided human performance is far from satisfactory Definitive diagnoses may be swiftly established. It is a uniquely clear-cut decision making domain, so if the technique is not of demonstrable benefit here its credibility in other clinical fields must be undermined

Systems for computer-aided diagnosis have three components Firstly, doctors record the relevant details (the indicants) on structured record sheets. For the acute abdomen these are symptoms and signs, but results of investigations can be handled in the same way. Secondly, these indicants are keyed into the computer, often (at least in trials) by some other person. The computer compares the present findings with a database and uses a statistical formula to calculate the diagnosis. Usually this is withheld until clinicians have made their own decision. The third component is some form of feedback. The relative contribution of forms, computers and feedback is immaterial to the pragmatic effect of the total 'package', but it is critical to explanations and policy decisions derived from trials

Key aspects of trial methodology are thus the structured data form, the formula for calculating the diagnosis, the database, the interaction with the computer, the audit feedback, the setting and design of the trial, and the presentation and interpretation of results.

Structured data forms

The quality of hospital records (especially casualty records) is uneven; important data are ambiguous, illegible or omitted Structured data collection constitutes a major change and may account for most benefits claimed for computer-aided diagnosis Note that baseline accuracy figures are culled from ordinary case notes, in which junior doctors often fail to record diagnoses. If these are marked 'wrong', accuracy will appear to rise when structured methods enforce this discipline In the UK multicentre study[3], clinical accuracy rose from 45·7 to 56·7 per cent with the use of forms alone, and to 65 per cent or more when computers or feedback were added. Similar rises were seen in Scottish[4] and Scandinavian[5,6] studies with no computer on site, the forms being sent to Leeds for analysis. Computer diagnosis and feedback would have been so long delayed that only the use of structured forms is likely to have affected results.

Calculating the diagnosis

Diagnoses have been calculated by Bayes' formula, other statistical methods such as discriminant functions, and artificial intelligence. Such methods calculate the likeliest diagnosis and do not deal in certainties. In contrast, the sort of classical (binary, Boolean or algorithmic) logic traditionally used by computers makes exact deductions ('If symptoms are A plus B then the disease is D') and has little relevance to clinical practice.

Most workers have used Bayes' formula, the modern version of which derives from probability theory and differs considerably from its 18th century ancestor. It assumes that:

(a) The patient has one (and only one) of the diseases known to the computer. (Yet there will always be patients with other diseases and multiple pathology is not uncommon. The surgeon can mentally set aside the dyspepsia or dysmenorrhoea to consider what symptoms remain unaccounted for by that background; Bayes' formula cannot.)

(b) Indicants are independent. (Yet many are highly correlated, such as 'site of pain at onset' with 'site of pain now'. Thus the computer either counts the same pain twice or misses the special significance of shifting pain.)

(c) The probabilities of all relevant diseases and indicants are known with sufficient precision. (See section on 'Database')

Bayes' formula contains a term $P(D_k)$ for disease frequency which many systems omit. This causes over-diagnosis of uncommon conditions; computer diagnosis of Crohn's disease[7] failed partly for this reason.

Discriminant functions have been used for the diagnosis of dyspepsia[8] and appendicitis[9] Each indicant is assigned a weighting factor. Then adding up the relevant indicants (weighing the clinical evidence, as it were) generates a figure x; if this exceeds a pre-set threshold the disease in question has been diagnosed Multiple pathology can be diagnosed by this method.

The promise of artificial intelligence remains unfulfilled. Systems using rule-based inference and 'fuzzy logic' have been tested on antibiotic therapy[10] and general internal medicine[11]. Their diagnoses were often catastrophically wrong and, therefore, their performance was unsafe.

0007–1323/89/010082–04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Methods have seldom been compared by matched trials. In 300 patients with upper gastrointestinal complaints, Bayes' and discriminant analysis were equally accurate[12], but only 11 symptoms were considered. Bayes' and rule-based inference had equal accuracy in 50 cases of dyspepsia[13]. In a trial of ten methods on 1991 cases of liver disease, Bayes' narrowly won[14].

No method is satisfactory. Bayes' is the best documented and no alternative has beaten it, at least for gastrointestinal disease. One would therefore expect any proponent of a new method to have made a matched comparison. Poor diagnostic methods limit the accuracy of the computer but do not invalidate trial results

Database

Key questions in assessing a database are the range of diseases covered, the indicants and the methods used to compile it.

Databases for the acute abdomen usually cover appendicitis, diverticulitis, perforated peptic ulcer, non-specific abdominal pain, cholecystitis, bowel obstruction and pancreatitis[15]. Renal colic and dyspepsia are added by some. The Leeds (UK) database for lower abdominal pain in women[16] covered ectopic pregnancy, ovarian cyst, appendicitis, incomplete abortion, pelvic inflammatory disease, urinary tract infection and non-specific pain.

The Leeds dyspepsia database covered chronic cholecystitis, duodenal ulcer, gastric ulcer, gastric cancer and functional (i.e., non-specific) dyspepsia; curiously, oesophageal conditions were omitted[17]. It is surprising how rigidly separate databases have persisted, despite the advantages of integration.

The acute abdomen database organized indicants into 33 groups with 135 possible replies[15]. Pulse and temperature, which are traditionally taught as informative signs, were notable omissions. 'History' was categorized as 'previous surgery' or 'no previous surgery' as if it were irrelevant whether the patient had had an appendicectomy, a hernia repair or a palliative operation for advanced malignancy. Likewise the categorization of 'drugs' as 'being taken/not been taken' was jejune There were no questions about past illness relevant to the present pain: known ulceration, Crohn's disease or gallstones. The criticism is not of the early workers' imperfect attempt, but the unthinking way in which similarly weak databases are still used.

The method of compiling the database will determine whether it can support valid diagnostic inferences. Critical points are the collection site, source record structure (or lack of it), the number of cases and the handling of 'zero' data. Generally data have been collected from hospital patients; they may not be valid for out-patients or cases seen at home by general practitioners. However geographical differences[18,19] do not appear important, at least within North America and Europe.

Early databases were collected from ordinary case notes, with all their omissions and ambiguities. Better data are obtained from structured records of consecutive, unselected patient series which trials of computer-aided diagnosis create as a spin-off. Such series have been collected for acute abdominal pain[18,19] but the list of indicants is still unrealistic.

The larger the series the more robust the data, though size does not overcome collection biases. More important than total size is the number of patients with each condition · 500 people with an acute abdomen might include only ten with pancreatitis. When thousands are available there may be benefits in subdividing some conditions. For instance the term 'non-specific abdominal pain' covers both constipation and gastroenteritis, so that the indicant 'bowel frequency', which is almost pathognomonic, becomes uninformative. If a certain indicant does not occur (e.g , no left loin pain in 100 cases of appendicitis) it cannot be set a probability of 0 per cent or its occurrence will absolutely rule out the disease. The value chosen should reflect confidence limits of the series Early databases contained many values of 0·1 per cent, which would have needed a sample size of 1000 to justify.

The early databases were flawed but creditable attempts; it is disappointing that later versions perpetuate many of their failings. Poor databases, like poor diagnostic methods, do not invalidate trial results but may limit the computer's accuracy.

Interaction with computer

Because Bayes' formula is so simple, and technology is progressing so rapidly, the computer hardware and software are largely irrelevant. More interesting is the doctor–machine interaction. Early computer systems were user-unfriendly, even within the limits of their technology, but modern equipment is outgrowing this problem. More seriously, systems offend clinical common sense. The example of drugs 'taken/not taken' has been mentioned, and similar absurdities abound. Systems generally request patient data in a rote sequence, deaf to the answers received. The sequence needs branches, to allow important detail to be pursued or superfluous questions to be skipped. Branches for dyspeptic or gynaecological symptoms, for instance, could merge the present separate databases.

In the UK multicentre study[3], doctors used the computer in 44·5 per cent of eligible cases, a further 29·6 per cent being entered by clerks. This overall figure conceals peaks and troughs; in Winchester it ranged from 64 per cent to below 10 per cent[20]. New junior doctors, it seems, start with enthusiasm but abandon the computer after a few months.

Thus, unfriendly systems may fail in three ways. Firstly, clinical data may be entered incorrectly. Secondly, such systems become disused and discredited. Thirdly, they may be anti-educational, for instance when recording previous surgery the doctor might put just 'yes' or 'no' in the case notes. It is not known whether these effects are significant.

The computer is only part of a package—yet it is the one item published papers highlight in their titles and in their concluding calls for more resources. But its specific contribution, over and above the effect of forms and feedback, remains ill-defined.

Audit feedback

Learning from experience should be part of routine practice. Feedback can take many forms, such as seeing the viscera at laparotomy, case discussions, or audit review of unit statistics. Units practise it to varying degree, and general practitioners and casualty doctors tend to miss out. One side-effect of a trial of any diagnostic technique—but not perhaps its service use—is to foster a comprehensive system of feedback and postgraduate education.

Few accounts of computer-aided diagnosis show in detail how and when feedback was given. It would be disastrous, for example, if a computerized score sheet of doctors' accuracy was seen as a substitute for proper case review. In Leeds, both clinician and computer accuracy fell when feedback stopped, recovering when it was reinstated[21], but the change appears not to be statistically significant. In the UK multicentre trial[3], junior doctors' accuracy rose from 56·7 to 64·8 per cent when feedback was added to forms, and to 68 per cent when computers were used as well. Learning curves rose more quickly with computers and at Winchester accuracy correlated with usage[20]. Perhaps the most striking result is the flat learning curve during the baseline period and when using forms alone. In other words, junior doctors in those units were no better after 6 months' training than when they arrived. This is a serious indictment of current training arrangements.

Trial design

It has often been unclear from publications which hypothesis, if any, is being tested. Key questions are:

Is the introduction of computer-aided diagnosis associated with useful change in clinical performance or patient outcomes?

Is the effect causal and, if so, which components are responsible?

Given the imperfect, incomplete data available at the time a clinical decision is required, can the computer generate a useful diagnosis/management decision in its own right, or is it simply echoing the clinician's opinion?

Four people typically assess the patient with abdominal pain: the patient him/herself, the general practitioner, the casualty officer and surgeon. In theory the computer could assist any of them but the acid test is how it performs on consecutive unselected cases. This usually requires a prospective design, although if structured patient records are in use, retrospective series may suffice. Note that if the series includes database cases, computer accuracy may be inflated. Trials on patients with selected diagnoses[22,23] are uninformative regarding performance on unselected patient populations.

The first decision in assessing an abdominal pain is the patient's own, to seek medical help. Computers have not been applied to this but in Glasgow they were used to pre-interview patients with dyspepsia[24]; the effect on process and outcome was not described In the Leeds area, structured pre-interviews were conducted by a non-medical assistant. Using this information, the computer was 81 per cent accurate on selected cases with dyspepsia[25] or with positive endoscopy findings[26] but scored only 65 per cent overall. Systems have been produced for use by crew of long-range submarines and spacecraft[27], but the quality of patient information was poor and computer accuracy was not stated

Computer-aided diagnosis has not been tested in general practice. Hospital studies imply that general practitioners have low accuracy on cases referred for surgical opinions[1,28], but this ignores patients managed without referral[29,30]. Each year in a list of 2000 patients, some 200 consult the general practitioner for abdominal pain, but only ten are sent to hospital as emergencies. Computer assistance is unlikely to better this performance

Casualty staff are similarly disadvantaged by ward-based studies as cases discharged without admission, on which their accuracy is highest, are ignored. Casualty staff were 45 per cent accurate in the initial Leeds trial[1] but 65 per cent accurate in a casualty-based study[31], as was the computer. The change largely reflects the method of measurement.

The striking feature of hospital-based studies is how few have actually tested computer assistance to clinicians Doctors have generally filled in structured forms and handed them to assistants for entry; the computer's diagnosis has been withheld and feedback delayed Only forms are tested by such trials.

Some trials have given the computer 'multiple guesses': the computer runs once with a surgical database, once with a gynaecological database, and so on, and the answer nearest to the final diagnosis is chosen in retrospect. This inflated computer accuracy from 55 to 70 per cent in casualty[31], and from 62 7 to 68·2 per cent in the multicentre study[3] Another biased practice is to mark the computer right when it is 'as near as it can get', for instance if renal colic is not in the database and the computer picks urinary tract infection instead[16]. The 'computer diagnosis' is normally the condition awarded the highest probability but sometimes printouts such as 'cancer 12 per cent, gastric ulcer 88 per cent' are taken as diagnosing cancer[32]. This is only valid if the lower threshold was set in advance

The patient's final diagnosis is crucial to evaluation; methods for establishing it have seldom been given in detail. If the trial aims are explanatory, diagnoses may need to match an explicit list of criteria. In a pragmatic trial (the majority) this is unnecessary, but ideally some independent blind observer should adjudicate on equivocal pathology results. Otherwise improvements in, say, negative appendicectomy rates may merely reflect altered scoring habits.

Presentation and interpretation of results

The simplest measure of performance is the number of correct and incorrect (or total) diagnoses, but even this has not always been given. Some accounts have given figures for selected subgroups, with overall scores being studiously ignored. Publications should also include full 'discriminant matrices', i.e. computer and clinical diagnoses *versus* final diagnosis Accuracy may vary markedly between different conditions, as will the consequences of mistakes. The full matrix reveals the system's sensitivity, reliability, specificity and diagnostic power.

It is astonishing how seldom doctors and computers have been directly compared on the same patient on the same occasion using the same indicants. Even when they have been compared, only summary data have been given; information on matching is lost and appropriate statistical tests (e.g. McNemar's test for paired binary data) cannot be applied In fact there has been a glaring lack of statistics, such as standard errors of accuracy rates, so that the significance of many results is unproved.

From some accounts the reader can derive standard errors and apply unmatched tests, which are weak but conservative. Correcting for biases of the types described earlier (where these can be quantified), the computer was significantly more accurate than clinicians in the initial Leeds trial[1,2], in gynaecological complaints[16], on X-ray appearances in Melbourne, Australia[8] and on right iliac fossa pain in Georgia, USA[33] Clinicians and computers were about equal in Sheffield (UK) children[34], whereas clinicians did better in Denmark[35], in casualty[31] and (marginally) in the UK multicentre study[3].

Computer and clinical accuracy have averaged about 65 per cent, a more realistic level than the early computer scores of 90 per cent. Even when the computer is more accurate than clinicians it is less safe, although it may be associated with improved clinical safety. In the UK multicentre trial clinicians' 'bad decision' rate fell from 6·3 to 2·7 per cent and their 'bad management' rate from 0·9 to 0·2 per cent.

Measures of performance or outcome include the proportion of patients sent home from casualty without admission, negative laparotomy rate, perforated/gangrenous appendix rate, and savings in bed nights or monetary costs. As with accuracy, results are often missing or selective. Thus the rates for perforated, gangrenous or normal appendix reported from Leeds[1] referred to the best batches; overall rates were not significantly better than post-trial figures. The Scottish study (effectively forms-only) saw major 'improvements'[4]; confusingly, baseline figures did not tally with those for the same hospital in a companion paper[28]. Yet if the effects described are real they are large enough to be of practical benefit. There is also a persuasive trend in the figures, suggesting a learning curve. The criticism is that trials have not been properly designed, either to quantify a desirable change or to determine its cause.

The best evidence to date comes from the UK multicentre study[3]. Computer-aided diagnosis was associated with improved negative laparotomy rates (from 313 to 174 a year), perforated appendix rates (from 23·7 to 11·5 per cent), shorter hospital stays (from 4 to 3 3 days for non-specific pain, 6·7 to 5·4 for appendicitis), and an estimated annual saving of 4258 bed nights. It is important to clarify the cause of these benefits, which occur 'downstream' of the computer system.

Annual National Health Service savings of between 20 million and 25 million pounds sterling have been extrapolated from these figures. Such claims are difficult to verify, especially as savings are marginal: only the patients who are least ill have their hospital stay averted or shortened, so that average costs mislead. Yet the benefits of computer-aided diagnosis still appear to out-weigh its costs, for instance operations are not avoided by missing serious conditions. So the question is which components merit further investment of time, money and effort On a rough economic analysis, structured forms are low cost, high gain, and the case for their introduction is strong. Computers are high cost, low gain, and the case for introduction is unconvincing; feedback is low cost, low gain, the case for introduction is borderline and merits further research.

Discussion

Clinical decision making for the acute abdomen is unsatisfactory, the rationale for computer assistance remains strong and initial results were spectacular. Yet today it is little used. Too often its introduction has been associated with poor trial design, bias, selective reporting of results, statistical naivety and spurious conclusions. One suspects that investigators who were dazzled by the prospect of 90 per cent computer accuracy, were disillusioned when they could not replicate this and lost sight of the practical benefits Those benefits have been exaggerated by biased methods, but neither this nor chance fully explains them

At least half the rise in clinical accuracy, and perhaps a similar proportion for outcome measures, stems from structured data forms alone. Statistical analysis suggested that feedback played a lesser role than computers[3], but the feedback in question comprised computerized score sheets not systematic case review. Outcomes and all but the initial diagnostic score are 'downstream' of both structured forms and computers, and it is difficult to see what is contributed by computer diagnosis *per se*. Its accuracy is inevitably limited by that of the clinician providing the input. In no way do current systems act as experts in their own right, and they are unlikely to do so until they possess the 'deep knowledge' of basic medical science that underlies the simplest surgical diagnosis. They appear merely to rehash the clinician's own opinion while losing overall accuracy.

The computer's accuracy may matter less than its credibility. For instance, it is heavily influenced by peritoneal and right iliac fossa signs. A disagreement over 'query appendix' might make the doctor ask 'Do I really think this patient is guarding?' and thus ponder the elicitation and interpretation of that sign. But this effect will be swiftly lost once the computer's dangerous inaccuracy is seen. Perhaps the computer's true role then is in undergraduate education, but this needs separate testing and there may be simpler roads to the same end.

The likeliest cause of the outcome effects is the system of case review which research into computer-aided diagnosis (but not necessarily its service use) enforces. It stimulates postgraduate teaching, introduces surgical audit in a non-threatening way, and highlights organizational problems such as delays in taking appendicitis cases to theatre and poor record keeping. It is these areas, plus the use of structured forms, which should be the focus of future studies. Basic research into better diagnostic methods must also continue, and the acute abdomen remains its natural test field. Meanwhile, computer-aided diagnosis is in no fit state to be widely implemented in the National Health Service.

In an ideal world one would not need the glamour of computers to attract professional interest and research funds to improving management of the acute abdomen. If, in our real world, computers are so needed as a 'loss-leader' then they have had some value. Yet over the last 15 years they have consistently diverted attention from important, solvable issues, and further investment in them is likely to show minimal or negative returns. If the Department of Health, UK now wishes to ensure that all the money and professional time devoted to this field is at last translated into real gains, it should consider a different strategy. It should monitor performance indicators for the acute abdomen, and require districts falling below target to introduce structured records.

A total of 61 patients with gastro-oesophageal reflux, resistant to medical therapy, were entered into a prospective randomized trial comparing the Angelchik antireflux prosthesis with Nissen's fundoplication. Both groups had a similar age and sex distribution and their reflux profiles were comparable. An Angelchik prosthesis was inserted in 30 patients and 31 underwent fundoplication. The mean duration of postoperative follow-up was 38 months. At clinical assessment 23 (77 per cent) of the Angelchik group were graded Visick grade I or II, compared with 29 (94 per cent) of the Nissen group. Assessment by 24 h pH monitoring and manometry between 3 and 6 months after operation showed that both procedures were equally effective in reducing reflux and increasing lower oesophageal sphincter pressure. However, long-term endoscopic follow-up revealed grade III oesophagitis in seven patients in the Angelchik group. No patient in the fundoplication group had grade III oesophagitis. Three of eight patients with strictures in the Angelchik group reported persistent dysphagia. All seven patients with strictures in the Nissen group were relieved of their dysphagia. Migration or erosion of the prosthesis did not occur. Three prostheses (10 per cent) were removed, two for dysphagia and one because of sepsis.

Keywords: Angelchik antireflux prosthesis, gastro-oesophageal reflux, Nissen's fundoplication, 24 h pH monitoring, oesophagitis

Controlled trials assessing the relative merits of antireflux procedures are rare[1–3]. Since Angelchik and Cohen first reported the results of their new surgical procedure for gastro-oesophageal reflux more than 25 000 Heyer–Schulte prostheses have been inserted[4] Although numerous subsequent reports have acknowledged the efficacy of the device in controlling reflux[5–7], only two groups reported the results of controlled clinical trials[2,3]. The uncontrolled nature of the majority of studies led to the adoption of extreme views, with the ease of insertion and the satisfactory results emphasized by some, while others stressed the alarming nature of the complications. In 1984 Bombeck pointed out that after the implantation of 14 500 prostheses 150 complications had been reported to the manufacturers[8]. He also pointed out that despite the spectacular nature of these complications the mortality rate was very low and that even if the complication rate was several times higher than that reported it was still a low complication rate relative to the number of prostheses inserted. Many of these complications were due to prosthesis migration, arising from a design fault which led to the tapes becoming detached The design of the prosthesis was improved by attaching the tapes circumferentially and between January 1982 and May 1985, 16 757 new-model Angelchik prostheses were used with only 6 (0·036 per cent) reported complaints[9]. Benjamin *et al* reviewed the complications of antireflux surgery and reported that the mortality and morbidity rates after insertion of the prosthesis were 0–<1 per cent, and 0–3 per cent, respectively[10]. These figures compare favourably with the reported mortality and morbidity figures for standard antireflux surgery, 0–4 per cent and 5–46 per cent, respectively[11–13].

Currently the most frequently used antireflux procedures are Nissen fundoplication, the Belsey Mark IV procedure, and Hill's posterior gastropexy. Comparative studies suggest that, of the three, fundoplication is the most satisfactory[1,14] but others have been less satisfied with the results of this operation[15]. It is evident that in order to evaluate the place of the Angelchik prosthesis in antireflux surgery the results of long-term controlled trials are needed. This paper reports our experience with the Angelchik prosthesis in a prospective controlled trial of the prosthesis *versus* Nissen fundoplication, with a mean follow-up of 38 months.

Patients and methods

Patients were admitted to the trial who had persistent symptoms of gastro-oesophageal reflux unresponsive to medical treatment Diagnosis was confirmed at endoscopy in all cases and supported by 24 h pH monitoring in the majority of cases. Manometry was performed where indicated to exclude motility disorders Oesophageal manometry was performed using a four-lumen polyvinyl catheter assembly with the four side holes spaced 5 cm apart from the distal end of the catheter and located 90° radially to one another The catheter assembly was perfused with a pneumohydraulic low compliance perfusion system and intraluminal pressure was transmitted via external transducers and recorded on a Devices* multichannel pen recorder The catheter assembly was introduced *per nares* in the fasting patient, passed into the stomach and withdrawn using a station pull-through technique until the high pressure zone was located at the distal oesophagus The lower oesophageal sphincter pressure was recorded as the difference between end-expiratory intragastric pressure and the maximal sphincter pressure at the respiratory reversal point. The sphincter pressure taken was the mean of 12 measurements performed on 3 pull-throughs.

After identification of the high pressure zone on manometry, the catheter assembly was withdrawn and an antimony-tipped pH electrode (Synectics Medical AB, Stockholm, Sweden) was positioned 5 cm above the high pressure zone Intra-oesophageal pH was recorded on a solid state Digitrapper (Synectics Medical AB) for a 24 h study period The 24 h pH data were stored and analysed on an IBM-PC computer using Synectics Esophagram version 5 09 software The data were analysed according to the total number of reflux episodes, total number of reflux episodes lasting longer than 5 min and the total time spent at pH 4 0 or less as a percentage of the study period

At laparotomy when the feasibility of both procedures was ascertained the patients were randomized by a closed envelope technique to undergo Nissen fundoplication or to receive an Angelchik prosthesis

All except one of the operations were carried out by the same surgeon (T.P.J.H.). Minimal dissection was used in placing the Angelchik prosthesis and after knotting the tapes the ends were secured with transfixion sutures rather than metal clips to avoid possible puncture of the prosthesis. When fundoplication was employed the aim was to provide a floppy wrap. The short gastric vessels were not routinely divided except when the spleen was high on the greater curvature. A 3 cm, 360° wrap was fashioned so as to admit easily a finger between the wrap and the oesophagus. Crural repair was carried out in both groups if the hiatus admitted more than three fingers. Three patients in the Angelchik group and two in the Nissen group underwent simultaneous cholecystectomy. One splenectomy was required in each group because of injury to the spleen. Patients with oesophageal strictures underwent dilatation at the time of surgery.

Postoperative follow-up was carried out by means of a questionnaire completed at outpatient review together with objective assessment by endoscopy, 24 h pH monitoring, and manometry.

A total of 61 patients were included in the trial. There were 30 patients in the Angelchik group and 31 in the fundoplication group. The mean age of patients in both groups was similar, being 50·1 years in the fundoplication group and 51·4 years in the Angelchik group. The male:female ratio in the fundoplication group was 18:13 and was 18:12 in the Angelchik group. The mean duration of symptoms was 4·7 years in the fundoplication group and 40·6 years in the Angelchik group. Both groups had similar pre-operative pH profiles (*Table 1*) and pre-operative manometric findings (*Table 2*). There were eight patients in the Angelchik group and seven in the fundoplication group with oesophageal strictures.

The mean duration of postoperative follow-up by means of questionnaire completed in the outpatients department (100 per cent response) was 38 months (range 18–56). Objective assessment by endoscopy, pH monitoring and manometry was performed at 3–6 months postoperatively. Further endoscopy was carried out for follow-up assessment of recurrent symptoms and therefore represents the current status of the patients.

Statistical evaluation of the differences in pH scores and sphincter pressures between the groups was by the Wilcoxon rank sum test for the analysis of non-parametric data. Evaluation of the differences in endoscopic and clinical grades was by χ^2, 2 × 2 contingency tables with Yates' correction.

Results

Clinical assessment

Of the patients in the Angelchik group, 23 (77 per cent) were either symptom free (Visick I) or had occasional mild symptoms which did not require treatment (Visick II); 29 (94 per cent) of the patients in the fundoplication group were graded Visick I or II. Of the seven (23 per cent) patients in the Angelchik group with poor results (Visick III or IV), severe and persistent dysphagia was present in three cases, and recurrent heartburn in five cases. One patient had both severe dysphagia and subsequent heartburn following oesophageal dilatation. In the two cases (6 per cent) in the fundoplication group with poor results (Visick III) this was due to recurrence of heartburn (*Table 3*). These differences did not reach statistical significance.

Oesophagoscopy

Postoperative oesophagoscopy was carried out in 25 of the patients in the Angelchik group and 24 patients in the fundoplication group. Of the 12 patients who refused postoperative endoscopy, 4 Angelchik patients and 6 fundoplication patients had a symptom status of Visick I, and 1 from each group was Visick grade II. Normal endoscopic findings were present in 16 patients in the Angelchik group and 19 patients in the fundoplication group. The remaining five patients in the fundoplication group had evidence of mild inflammation, whereas in the Angelchik group there were seven patients with moderate or severe oesophagitis and two patients with mild inflammation. These differences did not reach statistical significance.

24 h pH monitoring

Postoperative 24 h pH monitoring was carried out in 24 Angelchik patients and 21 fundoplication patients. Both groups showed a significant reduction in the severity of acid reflux

	Operative procedure		
Visick grade	Angelchik prosthesis	Nissen fundoplication	P value (Angelchik *versus* Nissen)
I	15 (77)	20 (94)	n.s.
II	8	9	
III	4 (23)	2 (6)	n.s.
IV	3	0	

Mean duration of follow-up is 38 months (range 18–56) Statistical comparison is by the χ^2 analysis· n.s., not significant. Percentages are given in parentheses

when compared with pre-operative findings. There were no significant differences in the pH profiles between the Angelchik and Nissen groups either pre-operatively or postoperatively

In the Angelchik group there was a significant postoperative reduction in the percentage of time that the pH was <4 (median 14·9, range 2·4–41·6, *versus* median 1·1, range 0–27 5) ($P < 0{\cdot}05$, Wilcoxon rank sum test). The percentage of time that the pH was <4 in the Nissen group was also significantly reduced (median 11·0, range 1 0–53·6, *versus* median 0·6, range 0–17) ($P < 0{\cdot}01$, Wilcoxon rank sum test)

The total number of reflux episodes was not significantly reduced after operation in the Angelchik group (median 42, range 13–158, *versus* median 18, range 0–76), but was significantly reduced in the Nissen group (median 48, range 6–133, *versus* median 7, range 0–94) ($P < 0{\cdot}01$, Wilcoxon rank sum test).

The number of reflux episodes which were longer than 5 min in duration was not significantly reduced postoperatively in the Angelchik group (median 9, range 0–25, *versus* median 1, range 0–13), but was significantly reduced in the Nissen group (median 5, range 0–25, *versus* median 0, range 0–7) ($P < 0{\cdot}01$, Wilcoxon rank sum test).

Of the 24 postoperative pH recordings performed in the Angelchik group, 5 were abnormal compared with only 2 abnormal recordings of the 21 performed in the Nissen group.

Lower oesophageal sphincter pressure

In both the Angelchik and Nissen groups, 21 patients had pre-operative oesophageal manometry performed Postoperatively, 22 patients in the Angelchik group and 19 in the Nissen group had manometry performed; the lower oesophageal sphincter pressure (mmHg) was significantly raised in the Angelchik group (median 13, range 5–40, *versus* median 35, range 15–70) and the Nissen group (median 12, range 5–40, *versus* median 30, range 12–45) ($P < 0{\cdot}05$, Wilcoxon rank sum test). There was no significant difference between the two groups in either the pre-operative or postoperative sphincter pressures.

Complications

There was no operative mortality in either group. The spleen was removed because of intra-operative injury in one patient in each group. One patient in the Angelchik group developed a subphrenic abscess which required operative drainage and the prosthesis was removed at the second operation. One patient in each group developed a pulmonary embolus. Both made a satisfactory recovery. There was one wound infection in the fundoplication group and one wound dehiscence in the Angelchik group

Complications specific to antireflux surgery were common. Transient dysphagia was common and occurred in 17 (57 per cent) of the Angelchik patients and in 12 (39 per cent) of the fundoplication group. Dysphagia persisted beyond 3 months in six patients in the Angelchik group. Three of these had pre-operative strictures and the dysphagia was mild. In the fundoplication group no patient had persistent dysphagia. Three patients in the Angelchik group had severe persistent dysphagia without a pre-existing stricture: the prosthesis was removed in two; the third patient refused further surgery.

Gas-bloat syndrome occurred with similar frequency in the two groups: ten patients (33 per cent) in the Angelchik group and nine (29 per cent) in the fundoplication group. Gas-bloat was defined as a clinical syndrome characterized by postprandial fullness, abdominal discomfort and a feeling of distension.

Complications specific to the Angelchik prosthesis, such as erosion, migration, and disruption of the prosthesis did not occur in this series.

Discussion

While it is evident from our results and those of others that the Angelchik prosthesis can increase lower oesophageal sphincter pressure and prevent gastro-oesophageal reflux, the mechanism by which the device achieves these results is not clear. Samelson *et al* concluded from studies in a canine model that the prosthesis acted by preventing distraction of the lower oesophageal sphincter by limiting gastric wall tension in the region of the gastro-oesophageal junction[16].

This study confirms the ability of the prosthesis to control reflux as determined by 24 h pH monitoring and oesophageal manometry. These objective assessments were performed between 3 and 6 months postoperatively and even at this early stage the fundoplication provided more effective control of reflux On longer follow-up the prosthesis was again found to be less effective than fundoplication in controlling reflux, and this was confirmed clinically by the return of symptoms and by the recognition of oesophagitis at endoscopy

Complications specific to antireflux surgery were seen in both groups of patients. However, these were more common in the Angelchik group. Dysphagia made removal of the prosthesis necessary in two cases. The incidence of early dysphagia with the prosthesis in the study by Gear *et al* was 38 per cent and resolution of the dysphagia occurred in all but two of his cases within a few months[2] On the other hand Wale *et al.* reported a 41 per cent incidence of long-term residual dysphagia[5]. We have found that more than half the patients experience some dysphagia after insertion of the prosthesis. However, the majority settle within a few months. In this series, 10 per cent had persistent dysphagia severe enough to warrant removal of the prosthesis, and of cases with pre-operative stricture only a minority obtained relief of their dysphagia. This is in contrast with the fundoplication group, in which no patient experienced severe persistent dysphagia and all those with pre-operative dysphagia obtained some relief of their symptoms.

Complications specific to the Angelchik prosthesis, such as migration and erosion into the gastrointestinal tract, have been widely reported by others but did not occur in this series.

Migration of the prosthesis has been reported by a number of authors[17,18] Migration has been of two types: proximal migration into the chest where angulation of the prosthesis may cause acute dysphagia, and detachment of the tapes, which allows displacement into the peritoneal cavity[19] The risk of proximal migration may be minimized by crural repair and detachment of the tapes has not been reported since the prosthesis was redesigned so that the tapes are attached along the circumference of the device.

Erosion of the prosthesis into the lumen of the alimentary tract has also been reported. This problem appears to arise in two situations. The majority have occurred when the prosthesis is placed adjacent to an alimentary tract suture line[20]. The risk is also present if the prosthesis is used after failure of a previous antireflux operation when, in the course of a difficult dissection, the abdominal oesophagus may undergo some trauma[21] The recommendation, therefore, by Durrans *et al.*, on the use of the prosthesis when previous surgery has failed should be treated with caution[22].

The effects of long-term implantation of prosthetic material in the abdominal cavity must also be considered. The longest reported follow-up of the Angelchik prosthesis comes from

Angelchik *et al.*[23]. No problems have emerged 10 years after implantation.

In this series, the Nissen fundoplication gave better results than the Angelchik prosthesis. Nissen fundoplication provided more permanent control of gastro-oesophageal reflux and dysphagia was less frequent and less persistent. However, complications of the Angelchik prosthesis such as migration and erosion can be avoided by proper case selection and careful operative technique.

Near-total thyroidectomy for carcinoma of the thyroid

There is controversy about the most appropriate treatment for patients with thyroid cancer. This study analyses our experience with 206 cases of thyroid cancer from an endemic goiterous area. There were 100 males and 106 females; patients presented at an earlier age with a short history. Thyroid cancers demonstrated an aggressive biological behaviour with an advanced stage at presentation (overt cancers in 51 per cent) and a relentless course with a mortality rate of 24·2 per cent for the well-differentiated tumours. Near-total thyroidectomy was performed in 126 patients. Multicentric foci of tumour were seen in 17·2 per cent of the well-differentiated cancers and 25·2 per cent of the cases of well-differentiated cancers who underwent near-total thyroidectomy developed loco-regional recurrence. Hemithyroidectomy was performed in 35 patients who refused completion total thyroidectomy at a second stage; 16·7 per cent of these patients developed a recurrence in the remaining contralateral lobe. Thus in our patients from an endemic goiterous area, near-total thyroidectomy is the treatment of choice particularly because of the frequent occurrence of follicular and anaplastic cancers (in 44·2 per cent) and because the course of the disease is more virulent.

Keywords: Thyroid carcinoma, total thyroidectomy

Carcinoma of the thyroid gland represents a spectrum of disorders differing in histological appearance and clinical behavior The surgical treatment for differentiated thyroid cancers varies from extremely radical[1] to conservative[2]. Controversy centres on the question of whether total thyroidectomy is required for adequate treatment of the differentiated cancers of the thyroid. The high incidence of multicentric foci in both papillary and follicular cancers[3] and the availability of radioactive iodine for both scanning and treatment of persistent or recurrent disease[4] are the reasons cited by proponents of the radical approach. However, advocates of a less radical approach believe that multicentric deposits of tumours within the thyroid can be ignored without clinical significance with a reported cancer recurrence rate of only 4·2 per cent in the remaining thyroid tissue following lobectomy[5] Further, they believe that total thyroidectomy may be accompanied by a significant morbidity rate, with a reported complication rate as high as 30 per cent[6]. Crile used the argument of the benign behaviour of thyroid tumours and the success of adjuvant thyroxine therapy ('thyroid feeding') for the residual gland as factors favouring a conservative approach for treatment of thyroid cancers[2].

The present study is a retrospective analysis of near-total thyroidectomy as a therapeutic modality for carcinomas of the thyroid gland. This study was necessitated by the finding, reported earlier[7], that thyroid cancers in our patients in north India have a greater degree of biological aggressiveness.

Patients and methods

The catchment area of the patients in the present series was the sub-Himalayan plains and areas in and around Delhi which are recognized iodine deficient areas[8] From 1970 to 1985, 206 thyroid cancers were treated by a single surgical service representing 17 4 per cent of all thyroid disorders managed during the period under review. Data of 163 patients have been presented earlier[8], this study includes the cases which were under review by the pathologist plus the cases operated on between 1983 and 1985

In the present study thyroid cancers, whether presenting as solitary nodules or as multinodular goitres, were classified as overt cancers if there was evidence of local invasion, lymph node involvement, recurrent laryngeal nerve palsy and/or distant metastasis. Malignancy was suspected if a thyroid swelling was accompanied by complaints of a recent, rapid increase in size and had a firm to hard consistency with or without pain and pressure symptoms, this is of particular relevance because of the large number of nodular goitres presenting to our outpatient department Patients with clinically benign solitary nodules and multinodular goitres in whom carcinoma was found on histology were also included. Before 1983 all cases of solitary thyroid nodules were operated on; since 1983 fine needle aspiration biopsy is routinely performed in all nodular goitres. Patients with reports of suspicious or positive aspirates for malignancy are operated on; other indications for operation being cosmesis and pressure symptoms.

Treatment of the differentiated thyroid carcinomas aimed at near-total thyroidectomy, i e both lobes and the isthmus were excised surgically and only a rim of posterior capsule was left around the parathyroid glands and the recurrent laryngeal nerve (which was identified routinely) on at least one side that was clinically free of disease. The operation was performed as a one-stage procedure in cases where thyroid cancer was documented before operation by histological or cytological examination In patients with a more uncertain diagnosis, especially those presenting as solitary thyroid nodule, a hemithyroidectomy (affected lobe plus the isthmus) was performed with completion of near-total thyroidectomy after receipt of histopathological results usually 7–10 days after the first operation The advantage of this procedure is that the adhesions are not fibrous and tissue planes can easily be identified. Completion of total thyroidectomy was not performed in those patients who after hemithyroidectomy refused a second operation A less radical procedure was performed in patients who presented with thyrotoxicosis and apparently benign multinodular goitres solely because in these cases carcinoma was a histological surprise, none of these patients had a completion of total thyroidectomy. Locally advanced cancers were merely biopsied

Results

The age and sex distribution of the 206 cases of thyroid cancers in the study group have been shown in *Figure 1*. The male to female ratio was 1:1·1 The average age of presentation was 39·7 years Thyroid enlargement was the commonest mode of presentation (90 per cent) and the average duration of this was 7 8 years (1 month to 20 years). Pressure symptoms (dysphagia

0007–1323/89/010090–03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

and dyspnoea) in 24 per cent and hoarseness in 22 per cent with a tender thyroid gland were seen frequently, especially with anaplastic cancers. Unilateral vocal cord palsy was recorded in five patients at presentation. Many patients (51 per cent) presented with overt cancers (*Table 1*).

Histopathologically papillary carcinoma constituted the predominant group (44·7 per cent); follicular carcinomas (28·0 per cent), medullary carcinomas (12·1 per cent), anaplastic carcinomas (11·2 per cent) and squamous cell carcinomas (3·9 per cent) occurred in the rest of the patients. A routine examination of the histopathological material revealed multicentric foci in 17 2 per cent of the cases.

At presentation lymph node metastases were recorded in 45·1 per cent of the cases (37·0 per cent of papillary and 34·5 per cent of the follicular carcinomas). Distant metastases had occurred in 27·6 per cent of the cases; lungs and the skeletal system were the most common sites for spread of the differentiated thyroid cancers.

Near-total thyroidectomy was performed in 62·1 per cent of the cases; in 19 cases the procedure was completed at a second stage. Among the 40 cases (19·4 per cent) who underwent hemithyroidectomy, 52·5 per cent were papillary and 22·5 per cent were follicular carcinomas (*Table 2*). Only one patient who underwent near-total thyroidectomy, died in the immediate postoperative period because of an associated cardiac disorder. Hypoparathyroidism was observed in 15/126 (11·9 per cent) but only four patients (3 2 per cent) required permanent supplement therapy. Permanent unilateral recurrent laryngeal nerve injury occurred in 5/126 (4·0 per cent). Since all patients with thyroid cancers routinely received suppressive doses of thyroxine after operation hypothyroidism did not occur. Only 1/35 cases (3·0 per cent) who underwent hemithyroidectomy developed unilateral recurrent laryngeal nerve palsy (*Table 3*).

In the patients who underwent hemithyroidectomy, recurrence in the remaining contralateral lobe was seen more frequently in cases of follicular carcinomas (*Table 4*). Loco-regional recurrence occurred more commonly in patients with papillary carcinomas. Mortality was high in all the histological types of thyroid tumours. Among the differentiated cancers 2/21 of papillary and 2/9 of follicular cancers who underwent hemithyroidectomy died, while 7/65 of papillary and 10/37 of follicular cancers who underwent near-total thyroidectomy died during the follow-up period. The difference was not statistically significant.

Discussion

The catchment area of the patients under study was the sub-Himalayan plains which are recognized iodine deficient areas[8]. Although thyrotrophin (TSH) has been considered to be an initiating factor for carcinoma of the thyroid in reports from endemic areas[9], the role of TSH in the pathogenesis of thyroid cancer remains obscure despite the finding of significantly higher levels of TSH in the carcinoma group[7]. However, reports

from endemic areas indicate a difference in the clinical and pathological features of thyroid cancers from those occurring in the iodine replete areas[8]. These features are evident from the present study where thyroid cancers occurred in younger patients and the history was shorter. A large percentage of the patients presented with advanced, fast-growing tumours In addition, there was a distinct histopathological difference in the type of these tumours when compared with reports from non-endemic areas; there being more follicular and anaplastic carcinomas with a consequent smaller proportion of papillary tumours. The aggressive clinical behaviour of the tumours is evident from the relentless progression of the disease and the high mortality among all histological types of thyroid cancers in this study. This finding is also reported by authors from other endemic areas[10] A plausible explanation for the aggressive biological behaviour of thyroid cancers in endemic areas may be found in reports by Crile[11,12], who suggested that continued TSH stimulation of these tumours may lead to transformation of differentiated, slow-growing, endocrine-dependent tumours to rapidly growing, autonomously functioning, metastasizing tumours. Keeping this natural history of thyroid cancers in our patients in perspective, we aimed always at near-total thyroidectomy for all histological types We also suggest that, especially in endemic areas with a high circulating level of TSH, an initial aggressive surgical approach for these tumours should be applied even when they present at an early stage of the disease.

Multicentricity is another important indication for total thyroidectomy in the population under study and is relevant for both follicular and papillary tumours[3,13]. Its incidence varies from 20 to 80 per cent in different series depending on the perseverence of the pathologist[14]; a routine examination of the excised specimens in our patients revealed multicentric foci in 17·2 per cent of the well-differentiated tumours. Further, 16·7 per cent of the patients who underwent hemithyroidectomy in the study group developed recurrence in the remaining contralateral lobe This recurrence rate is usually reported as between 3 and 8 per cent, but has been reported as high as 24 per cent[15]. The significance of this finding is emphasized by Tollefsen *et al.*[16], who found that most deaths from papillary carcinoma resulted from persistent or recurrent disease in the neck after initially inadequate surgical treatment.

An additional factor favouring total thyroidectomy is the reported transformation from well-differentiated tumours to anaplastic and squamous cell carcinomas[17–19] which are recognized for rapid growth, local invasion and a shortened life expectancy. Follicular carcinomas are reported to be more commonly associated with anaplastic tumours. We have earlier reported this association in cases of squamous cell carcinomas[20]. Further, thyroglobulin$^{(Tg)}$ levels can be used after total thyroidectomy to screen for recurrent or persistent disease[21].

The risk of an increased complication rate is sometimes considered a contra-indication to total thyroidectomy[22–24]. Recurrent nerve damage is reported at an incidence of up to 23 per cent[22] and hypoparathyroidism in up to 29 per cent[25]. The habit of performing near-total thyroidectomy with preservation of the posterior capsule has minimized complications[4,25] Using this operative technique we observed recurrent laryngeal nerve damage in 4·0 per cent and permanent hypoparathyroidism in 3·2 per cent of our patients who underwent near-total thyroidectomy

The added advantage of near-total thyroidectomy for patients from poorer socio-economic strata in our study is the ability to perform an immediate postoperative evaluation of disseminated disease with radioactive iodine and to implement treatment This is important as we find that many of the patients are irregular in follow-up and when they return with recurrence, the disease may be so advanced as to negate the value of further therapy This is an innate problem of all developing countries and any management plan must be not only clinically optimal but also take account of the socio-economic and cultural characteristics of the population.

Contrast enhanced CT scan as a diagnostic procedure in mesenteric ischaemia due to mesenteric venous thrombosis

P.-A. Clavien, O. Huber, D. Mirescu* and A. Rohner

*Department of Surgery and *Radiology, University Hospital, 1211-4 Geneva, Switzerland*
Correspondence to: Dr P.-A. Clavien

Mesenteric infarction resulting from mesenteric venous thrombosis is a difficult diagnosis which should be differentiated from other causes of bowel infarction[1]. Clinical presentation and intra-operative findings are often characteristic[1,2]. Most authors stress the importance of arteriography to assess the aetiology of mesenteric infarction and define the site of arterial occlusion[3–5]. However, mesenteric venous thrombosis is often not recognized at arteriography and appears difficult to distinguish from non-occlusive infarction. Contrast-enhanced CT scan, which has been demonstrated as useful in the evaluation of portal thrombosis[6] or portal cavernoma[7], represents an interesting and non-invasive alternative for the diagnosis of venous mesenteric infarction[8].

We report four cases of mesenteric infarction which have been diagnosed by contrast-enhanced CT scan, either pre-operatively (case 1 and 2), to confirm an intra-operative diagnosis (case 3), or as a means of follow-up of conservative therapy (case 4).

Patients

Case 1

A 29-year-old man, HIV seropositive and a morphine addict, presented with a 5-day history of cramping abdominal pain and vomiting. Two weeks previously a splenectomy was performed for an immune thrombocytopenia resistant to medical treatment. On examination, he was ill, febrile to 38°C and had an abdomen which was diffusely tender. Initial investigations revealed a white cell count of 32×10^9/l with 87 per cent polymorphonuclear leucocytes and a normal platelet count. A contrast-enhanced CT scan performed in search of an intra-abdominal abscess showed typical findings of venous mesenteric infarction: namely a mesenteric venous thrombosis (*Figure 1a*), thickening of the intestinal wall, a valvulae conniventes localized to an ileal loop and ascites (*Figure 1b*). The diagnosis was also confirmed by selective angiography and subsequent laparotomy. He was successfully treated by wide resection (60 cm of ileum) and intravenous heparin in therapeutic doses. Furthermore, an isolated and persistent protein S (a protein C cofactor) deficiency of <20 per cent was demonstrated.

Case 2

A 44-year-old man, treated in the last 4 years for chronic pancreatitis, was referred with abdominal pain, haematemesis and splenomegaly. Examination revealed slight tenderness and guarding of the upper abdomen with diminished bowel sounds. The white cell count was 18×10^9/l associated with an erythrocyte count of 5500×10^9/l. Gastroduodenoscopy was normal. A contrast-enhanced CT scan showed massive splenomegaly, pancreatic calcification, a small pseudocyst in the pancreatic tail, portal and mesenteric venous thrombosis, portal cavernoma, thickening of a middle jejunal loop, and peritoneal fluid. Laparotomy demonstrated haemorrhagic ascites and venous mesenteric infarction involving about 70 cm of jejunum. The patient was successfully treated by wide intestinal resection and full dose heparin anti-coagulation. Later on, haematological investigations revealed a polycythaemia rubra vera.

Case 3

A 75-year-old man presented with a 1 week history of intermittent upper abdominal pain associated with bloody diarrhoea. Two years previously he had complained of the same symptoms. At this time, despite extensive investigations which included gastroduodenoscopy, colonoscopy, barium meal and enema, the diagnosis remained elusive and he was treated conservatively. On admission, physical examination revealed a distended abdomen with slight diffuse tenderness and absent bowel sound. The white cell count was 9×10^9/l. Except for a plain abdominal X-ray no pre-operative investigation was performed. At laparotomy a sero-sanguineous peritoneal fluid and typical venous mesenteric infarction involving 60 cm of proximal ileum were found; a wide resection was undertaken. Twelve hours postoperatively a contrast-enhanced CT scan clearly showed a mesenteric venous thrombosis which confirmed the intra-operative macroscopic diagnosis. With full-dose intravenous heparin treatment, the postoperative course was uneventful. No predisposing factors could be found in this patient.

Case 4

A 54-year-old Italian with a history of multiple admissions for deep

vein thrombosis and pulmonary emboli was admitted with several months of intermittent upper abdominal pain with nausea, vomiting, and diarrhoea. On examination the patient had a low-grade fever and his abdomen was diffusely distended. Occult blood was found in the stool. The white cell count was 19×10^9/l. Plain abdominal X-ray was uncharacteristic and endoscopy showed grade 2 oesophageal varices. A contrast-enhanced CT scan showed a portal and mesenteric venous thrombosis (*Figure 2a*) with thickening of a middle jejunal loop (*Figure 2b*). On conservative treatment, serial CT scans showed regression of the jejunal thickening which had totally disappeared 2 weeks later (*Figure 2c*). Anticoagulation in therapeutic doses was contra-indicated on the grounds of persistent oesophageal varices. During the following 2 years he presented with two similar episodes which were both treated conservatively and documented by serial CT scans. Recently, he had the first episode of acute bleeding from oesophageal varices which were treated by sclerotherapy. A liver biopsy confirmed the absence of cirrhosis. A persistent AT III deficiency to <60 per cent was found. Screening of the patient's family for AT III was not possible. Thus, it remains unclear if this deficiency was congenital or acquired.

Discussion

Clinical presentation of mesenteric infarction due to mesenteric venous thrombosis is suggestive of the diagnosis when a history of deep vein thrombosis or lung emboli with long and intermittent abdominal pain are present[1-2]. On examination, mesenteric venous thrombosis is not distinguishable from other causes of infarction[1]. Arteriography is indicated when an arterial aetiology is suspected as it undoubtedly offers the best assessment of the mesenteric vascular anatomy, which is useful if revascularization is necessary[3-5]. However, knowledge of the precise anatomy of venous thrombosis is not necessary since revascularization is not indicated in venous mesenteric infarction[1,2,5]. In addition, visualization of the venous thrombosis at arteriography requires an experienced radiologist and is time consuming[1,8-10].

Contrast-enhanced CT scan is a non-invasive modality which represents an interesting alternative to arteriography. Mesenteric venous thrombosis is easily recognized, presenting with hypodensity in the trunk of the superior mesenteric vein, and its association with peritoneal fluid, thickening of the intestinal wall and valvulae conniventes localized to a jejuno-ileal segment constitute a typical triad for venous mesenteric infarction. When the diagnosis is clinically suspected, CT scan should be performed as an emergency procedure in order to confirm the diagnosis. If the above triad is present, further investigations are unnecessary before laparotomy. Most commonly, the venous aetiology is only suspected at laparotomy on the basis of serosanguineous peritoneal fluid, typical appearance of the gut and its mesentery with normal arterial pulsations[1,2]. Contrast-enhanced CT scan appears to be the procedure of choice to confirm the diagnosis postoperatively. Case 4 illustrates that, in case of conservative treatment, serial CT scans can be extremely useful to monitor the evolution of the affected bowel. Furthermore, CT scan aids in the detection of other important intra-abdominal conditions which represent predisposing factors, namely liver cirrhosis, intra-abdominal abscess, acute and chronic pancreatitis.

Facial paralysis due to a benign parotid tumour

D. Whillis, J. R. Goepel and A. J. Shorthouse*

*Weston Park Hospital and *Royal Hallamshire Hospital, Sheffield, UK*

Correspondence to: Dr D. Whillis, Weston Park Hospital, Sheffield S10 2SJ, UK

Traditional surgical teaching is that in cases of parotid swelling, facial nerve involvement is 'proof positive' of carcinoma[1]. This is misleading[2-8], and leads to an unduly confident diagnosis of malignancy in the absence of pathological support. We report a patient with a parotid swelling and paresis of the ipsilateral facial nerve; the lesion subsequently proved to be benign. A cause for the paresis is postulated and other similar cases from the literature are reviewed. We now consider pre-operative assessment, despite its difficulties, essential in the management of patients with a parotid swelling.

Case report

A 67-year-old woman presented with a 1 week history of left facial weakness and associated nerve root pain. A painless left pre-auricular swelling had been present for 4 months. On examination, there was a 6 × 4 cm firm mass in the left parotid region, fixed deeply but not to skin. There was no associated lymphoadenopathy. In addition, there was an obvious left lower motor neurone VII nerve palsy affecting all branches of the nerve. In view of the associated facial paralysis, a clinical diagnosis of a malignant parotid tumour was made.

A radical total parotidectomy was performed. The mass was confined to the deep part of the parotid gland without local infiltration so it was removed with a wide excision taking in adjacent lymph nodes, the upper part of sternomastoid and the posterior part of the masseter muscle. The facial nerve was divided near its exit from the skull.

Pathology

The parotid gland was partly replaced by a cystic mass containing thick yellow-green pus. Histological examination showed a Warthin's tumour with marked cystic change and partial necrosis. Focal squamous metaplasia was present, in places associated with dense fibrosis of the stroma. Large nerves were stretched around the margin of the cyst between it and the remaining salivary tissue. Small nerve branches showed degeneration where trapped in fibrous or inflammatory tissue. The cyst contained neutrophil polymorphs and Gram-positive organisms. There was no evidence of malignancy.

Discussion

There is a traditional triad of physical signs associated with parotid swellings, any one of which is considered adequate for the clinical diagnosis of malignancy[2]. These are: (1) demonstrable metastases, (2) invasion of adjacent structures, and (3) spontaneous facial palsy. Although facial palsy is considered to be a reliable physical sign, there are six previous reports of facial nerve paralysis occurring with benign parotid tumours. In one case, nerve damage was caused by haemorrhage into a cyst[3]; the authors postulated increased pressure on the facial nerve. In most of the other cases the tumour was a pleomorphic salivary adenoma with or without cystic change[4-6]; in another case it was an oncocytoma[7].

There is only one other report of a facial palsy associated with a Warthin's tumour[8], and we believe the pathogenesis in our case to be similar. We consider that infection occurred in an infarcted cystic adenolymphoma, with nerve damage occurring as a result of stretching the nerve round the cyst and additional inflammation and infarction.

We now favour pre-operative assessment of parotid swellings despite the difficulties, which are mainly those of distinguishing between benign and malignant tumours. Parotid sialography is of limited value[9] and, although computed tomography is accurate in detecting tumours in and around the parotid, it is unable to distinguish between benign and malignant lesions[10]. Peroperative frozen section diagnosis is not completely reliable owing to sampling errors or the co-existence of more than one pathological entity[8,11]. Also dissemination of tumour cells may occur, increasing the risk of local recurrence. This is not the case, however, with fine needle aspiration biopsy; although there is the risk of a false negative result[12] the procedure is simple and without significant morbidity. Ultrasonography may be of value in pre-operative assessment, and indeed the appearance of adenolymphoma may be characteristic[13]. Occasionally open biopsy with subsequent delayed primary surgery may be required.

At the present time we would recommend fine needle aspiration and ultrasound examination in all cases of parotid swellings presumed to be malignant on the basis of facial nerve palsy. The rare occurrence of a benign cystic swelling might be identified, and if needle aspiration is performed may also allow recovery of the palsy. A careful dissection with preservation of the nerve might also be followed by some recovery of function.

Where the diagnosis remains doubtful, the tumour must be assumed malignant. Despite the remote possibility of benign disease, a radical parotidectomy with sacrifice of the facial nerve should be performed. The presence of facial nerve paralysis in a malignant parotid tumour is a poor prognostic sign[14], and significant efforts should be made to avoid the considerable problems of locally recurrent disease.

Plunging salivary glands

J. D. Maynard

Medical and Dental School, Guy's and St. Thomas' Hospitals, Gordon Museum, Guy's Hospital, London SE1 9RT, UK
Correspondence to: Mr J. D. Maynard

Patey[1] first drew attention to the disappearing parotid tumour. As he pointed out, the 'plunging goitre' is a familiar phenomenon. The goitre partly lying in the mediastinum rises into the neck on deglutition and particularly on forced expiration against a closed glottis.

Five years ago the author was confronted with a parotid tumour that disappeared under anaesthetic and 4 years ago with a 'plunging' submandibular salivary gland. Two months ago a 3 cm hard mobile parotid tumour disappeared between the ward and theatre.

Case reports

Case 1

A man aged 70 years was seen with a discrete mobile and rather soft lobulated mass measuring 3 × 2 cm in the lower pole of the right parotid. A possible diagnosis of adenolymphoma was made and admission arranged.

When the patient was seen in the anaesthetic room after the induction of general anaesthesia, the tumour had disappeared. After checking the patient's notes and, fortunately, being aware of Patey' s experience, we explored the right parotid through a routine parotidectomy incision. The facial nerve was identified at its bifurcation and the apparently normal lower pole of the parotid was mobilized. During this manoeuvre the tumour reappeared from behind and deep to the angle of the jaw. It was apparent that the tumour was arising from the lower part of the deep lobe of the parotid. Thus, forewarned that the lower branch of the VIIth nerve would be superficial to the tumour, this branch was dissected without injury and the lower part of the deep lobe and the lower half of the parotid was excised with the contained tumour. There was no postoperative facial palsy and histology confirmed that the tumour was an adenolymphoma. There were no other complications.

Case 2

A man aged 31 years was found to have a hard discrete mobile swelling measuring 3 cm in diameter just anterior to the left submandibular gland. It was thought to be a submandibular lymph node or even a rare submandibular gland neoplasm. It was explored at another hospital and the left submandibular gland excised without incident. The next morning the swelling was still present. The excised salivary gland, although large, was normal. The patient was referred for a second opinion and reoperation was requested.

At operation an incision was made over the tumour and extended posteriorly into the previous incision. After incising the platsyma, the tumour disappeared and the operative site appeared completely empty. A finger was inserted into the mouth and the tumour was found under the mucosa of the floor of the mouth. It was easily displaced into the submandibular wound and removed without difficulty. Microscopically, it was found to be a neurofibroma. There were no postoperative complications.

Case 3

A 56-year-old woman was seen in out patients with a 3 cm hard mobile mass in the lower pole of the right parotid gland. She thought it had been there for at least 18 months, but had a vague idea it had been present before this but had disappeared. We unwisely discounted this information.

When the patient reached the operating theatre no tumour was palpable in her apparently normal parotids. The notes confirmed the side of the vanishing tumour and the gland was explored. Before identification of the VIIth nerve there was again no evidence of tumour on repeated palpation. The nerve was identified and forward mobilization of the superficial lobe of the gland commenced. At this stage it became apparent that there was a mass deep to the main branch and bifurcation of the facial nerve. On further traction a deep lobe tumour, anterior and deep to the styloid process, was defined and once more became the obvious superficial tumour that had presented clinically in the out patients. It was excised with the lower pole of the parotid. There were no postoperative complications and the VIIth nerve was intact. Histological examination showed the tumour to be a pleomorphic adenoma.

Discussion

Patey, having previously described the dumb-bell tumour of the parotid[2], in which a deep tumour becomes imprisoned in the lateral pharyngeal space, considered that the tumour in his case had so stretched the margins of the space as to present superficially. The muscular relaxation under general anaesthetic had allowed the tumour to retreat to the site of origin and apparently disappear. The same explanation suffices for the two parotid tumours described here.

The submandibular tumour had arisen in the region of the sublingual gland in the floor of the mouth superior to the mylohyoid but had prolapsed behind the free posterior border of the mylohyoid and became visible and palpable in the submandibular region inferior to the muscle. The muscular relaxation consequent on general anaesthesia had allowed the tumour to slip out of the operative field to the superior surface of the mylohyoid where it was readily palpable in the floor of the mouth.

Pseudoachalasia after radical gastrectomy

L. J. Yeoman, A. Grundy, M. C. O. Parker* and A. G. T. W. Fiennes*

*Departments of Diagnostic Radiology and *Surgery, St. George's Hospital, Blackshaw Road, London SW17 0QT, UK*

Correspondence to: Dr A. Grundy

Pseudoachalasia, or secondary achalasia, is a rare condition suggestive of underlying malignancy in which the oesophagus shows abnormalities identical to primary idiopathic achalasia with respect to the clinical, radiographic, endoscopic and manometric findings. The malignancy is usually an adenocarcinoma of the stomach or, less commonly, a non-gastrointestinal malignancy[1–16].

We report the case of a patient who had a radical total gastrectomy with oesophagojejunostomy for an adenocarcinoma of the stomach. This patient subsequently demonstrated radiological and endoscopic features of achalasia, although these were not present at the time of presentation of the carcinoma.

Case history

A 69-year-old man presented with breathlessness and anaemia. A double-contrast barium meal revealed a tumour high on the lesser curve of the stomach, which was confirmed by endoscopic biopsy to be an adenocarcinoma.

A radical total gastrectomy, splenectomy and distal pancreatectomy with omentectomy was performed. A stapled oesophagojejunal anastomosis with a Roux-en-Y loop was fashioned. Histological examination of the resected specimen showed a moderately differentiated adenocarcinoma. The resected margins were free of tumour but lymph nodes from the greater curve and lesser curve contained metastatic tumour.

The patient remained well until 6 months later when he was re-admitted to hospital with postprandial vomiting. There was no dysphagia and appetite was preserved, although weight loss of 5 kg over the preceding month was documented.

A barium meal demonstrated a functional obstruction of the lower oesophagus with a smoothly tapered narrow segment, which opened only when an adequate column of barium produced sufficient pressure (*Figure 1*); the appearances resembled achalasia. There was no evidence of stricture at the anastomosis or of tumour recurrence and barium passed freely into the jejunal loop.

At endoscopy the lower oesophagus was thought to be slightly rigid but otherwise normal. The jejunum was entered easily and appeared normal. Biopsies from the anastomosis and adjacent mucosa showed no evidence of malignancy or inflammation.

Balloon dilatation of the distal oesophagus was performed and the lower oesophagus dilated readily. A repeat barium swallow 6 days later showed some improvement with less lower oesophageal spasm, although the appearances still resembled achalasia.

A small bowel meal via a tube introduced into the efferent loop suggested extrinsic compression 15 cm from the anastomosis site. At laparotomy there was extensive peritoneal disease with encasement of the lower end of the oesophagus by plaque-like tumour. There was no possibility of palliative surgery.

The patient died postoperatively and post-mortem examination was not performed.

Discussion

Primary achalasia is a motility disorder of the oesophagus of unknown cause.

On barium studies achalasia has characteristic features. There is failure of relaxation of the lower oesophageal sphincter with the lower end showing smooth symmetrical narrowing. In the horizontal position barium does not pass into the stomach, but in the upright position the barium column is retained above the lower oesophageal sphincter until its hydrostatic pressure overcomes the resistance and barium squirts into the stomach.

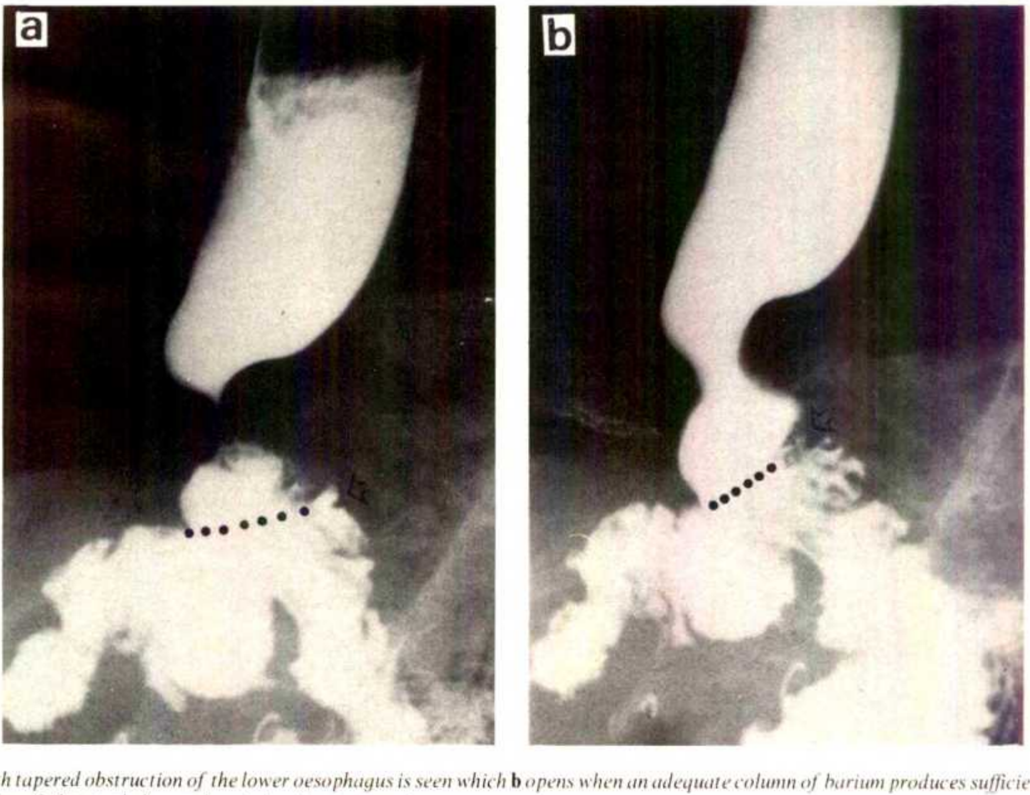

Figure 1 **a** *Smooth tapered obstruction of the lower oesophagus is seen which* **b** *opens when an adequate column of barium produces sufficient pressure. Dots indicate the position of the stapled oesophagojejunal anastomosis*

0007–1323/89/010097–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

However, the sphincter closes before the oesophagus is empty. There is a reduction in peristalsis, initially in the lower two-thirds and eventually throughout the oesophagus, although unco-ordinated contractions may be seen. The oesophagus is usually dilated to a variable degree[17,18].

At endoscopy the oesophagus is usually dilated and aperistaltic and the endoscope passes easily into the stomach through the lower sphincter[19].

In secondary achalasia the above characteristics are mimicked, but the condition is temporally and apparently causally associated with a malignancy[1]. This is most commonly adenocarcinoma of the stomach[1–10], but has been described with gastric lymphoma[12], bronchogenic carcinoma[1,11,13], carcinoma of the pancreas[1], hepatoma[11], carcinoma of the prostate[14], Hodgkin's disease[15] and reticulum cell sarcoma[16]. In cases of secondary achalasia associated with gastric carcinoma it may be difficult or impossible to detect the presence of the malignancy on barium study, endoscopy or even manometry. Inhaled amyl nitrite after barium swallow has been used to help distinguish achalasia from pseudoachalasia as the lower sphincter relaxes in the primary but not in the secondary form[20].

In our patient the past history of adenocarcinoma of the stomach was known. However, in patients who present *de novo* with achalasia malignancy must be considered.

Secondary achalasia, which has a functional neuromuscular basis, must not be confused with the effects of an organic mechanical obstruction due to annular infiltration or a mass. In this situation, unlike achalasia, peristalsis is present and can be seen during barium swallow. Also the narrowed segment is rigid and does not distend with the transition zone between normal and abnormal oesophagus being sharply defined. The mucosa may be ulcerated and a tumour mass may be seen[18]. It has been suggested that swallowing an effervescent agent after the barium helps in the distinction between functional and mechanical obstruction as the oesophagus will then empty in the former but not in the latter[18]. At endoscopy the endoscope will not pass through, or will only do so with some difficulty when severe narrowing is of organic origin rather than functional[19].

The pathophysiology of secondary achalasia is unclear. Several mechanisms have been proposed: a non-specific reaction to obstruction; carcinomatous involvement of the oesophageal myenteric plexus; invasion of the vagus nerve or its dorsal nucleus; or a paraneoplastic effect equivalent to peripheral neuropathy and central nervous system syndromes seen with certain carcinomas, not due to direct invasion or metastases[2,3,11].

The treatment of secondary achalasia is aimed at the primary tumour and patients have been reported in whom a return of peristalsis has followed surgery, radiation therapy and chemotherapy[6,12,13,16] although such improvement is not invariable[15]. It would appear that dilatation of the narrowed segment by bougie or balloon tends to result in little or transient improvement[2,7]. Thus for patients with metastatic disease where there is no appropriate treatment for the primary disease, there seems to be no satisfactory treatment of the secondary achalasia at present.

Heller's myotomy with partial fundoplication

P. F. Crookes, A. J. Wilkinson and G. W. Johnston

Royal Victoria Hospital, Belfast BT12 6BA, UK
Correspondence to: MR G. W. Johnston

Although achalasia is often treated by endoscopic dilatation, some patients still require a Heller's myotomy. The operation carries a low mortality and morbidity risk and the results are satisfactory in 80–90 per cent of patients. However, many operative details remain unresolved, including argument over abdominal or thoracic approach, the length of the myotomy on the oesophagus and stomach and whether or not an antireflux procedure should be added. Those who oppose the addition of an antireflux procedure claim a low incidence of gastro-oesophageal reflux following myotomy alone and point to the potentially obstructing nature of a fundoplication surrounding an aperistaltic oesophagus[1]. Other workers report a higher incidence of reflux following myotomy alone and some of these patients with reflux go on to develop oesophageal strictures[2]. In a small group of 17 patients previously treated by Heller's myotomy in our own unit, three developed oesophageal strictures out of a group of 11 patients treated by myotomy alone, whereas there were no strictures in six others in whom a full 360° wrap was added. The technical difficulty of doing a secondary fundoplication at a further operation in patients with stricture due to reflux prompted a modification to Heller's myotomy. The aim was to avoid the problem of reflux stricture on one hand and the risk of postfundoplication dysphagia secondary to a 360° wrap on the other. We report on the early results of the first seven patients treated by this method.

Patients and methods

Since May 1984, seven consecutive patients were treated for achalasia. All had typical radiological and manometric evidence of achalasia. There were five men and two women; the age range was 22–66 years. The operation was performed through the abdomen and the myotomy carried out for a distance of 5–7 cm above and 1 cm below the oesophagogastric junction. A modified fundoplication was added, in which the edges of the fundal wrap were sutured, not to each other but to the cut edges of oesophageal muscle for a distance of 2·5 cm on either side, using 2/0 interrupted linen (*Figure 1*). The cut muscle gives an excellent bite for the sutures and allows the mucosa to bulge out freely. Length of follow-up has been 1–3·5 years and included oesophageal manometry and prolonged ambulatory pH monitoring.

Results

There were no mucosal perforations. Postoperative recovery was satisfactory, and all patients were discharged by the tenth postoperative day. All patients were completely relieved of dysphagia for solids and liquids. None has developed any symptoms of reflux in the follow-up period. Pressure studies and prolonged pH monitoring are available for six of the seven patients. The other patient emigrated to Canada but reports to be free of dysphagia and heartburn. Manometry shows a small high pressure zone in the lower oesophagus in all of the six patients studied and this may represent the site of the fundoplication. The pH monitoring shows that five out of six patients are free of significant reflux. However one patient does show evidence, on pH monitoring, of nocturnal reflux with one sustained episode between 02.00 and 04.00 hours. This patient denies any symptoms of reflux on careful questioning.

Discussion

Despite the generally satisfactory results of Heller's myotomy in achalasia, most workers report a proportion of cases where dysphagia remains or returns, or where troublesome reflux develops[2–5]. In some cases this may not be related to surgical technique: operations on advanced cases with megaoesophagus do less well, carcinoma may develop, or the original diagnosis may have been incorrect. However in a substantial number of failures technical problems are responsible. Thus the oesophageal myotomy may have been inadequate in depth or length, the gastric portion of the myotomy too extensive, the cut edges may have healed in opposition, or gastro-oesophageal reflux with stricture may have occurred[6,7]. The true incidence of reflux following surgery for achalasia is unknown as not all workers specifically look for it. In particular, few studies using the sensitive method of prolonged ambulatory pH monitoring have been reported. Ellis and colleagues report significant reflux symptoms in only four of 113 patients treated by myotomy alone[8]. They attribute their low complication rate to the shortness of the myotomy on the gastric side (≤1 cm) and the minimal disruption of the diaphragmatic attachments afforded by the thoracic approach. However they do not advance data to substantiate this claim. Only 18 of their 113 patients were studied postoperatively by pH testing and eight of these patients had documented reflux. The method of pH testing is not specified. A similar claim was made in a recent review by Andreollo and Earlam[9] in which the results of more than 5000 operations were discussed. In many of the studies cited the results do not support their conclusions. Postoperative reflux was reported in 20·8 per cent[10], 35·2 per cent[11] and 23·6 per cent[12] of cases in studies where the myotomy was performed through the preferred thoracic approach. Other studies cited in this review are oversimplified; in one paper where operations were classified by the reviewer as thoracic, approximately half were done via the abdomen and the authors stated that 'there were no differences in results following either approach'[2]. The literature does not therefore support the view that optimal results are obtained by myotomy alone performed through the chest. There are further strong arguments in favour of doing an antireflux procedure as part of the original operation. For example, if reflux develops in an aperistaltic oesophagus, clearing time is much prolonged and stricture formation con-

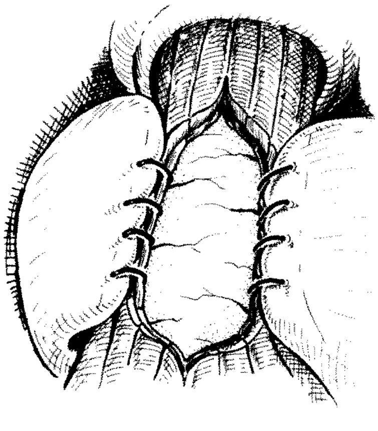

Figure 1 *Modified fundoplication*

0007–1323/89/010099–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

sequently more likely. Also, if a second operation is required, the dissection is more difficult and the risk of perforation of the unprotected mucosa is increased. Most published reports show a higher incidence of unsatisfactory results in patients requiring reoperation.

In this context, the initial results of our modified Heller's operations are encouraging, in that all seven patients are completely asymptomatic and gastro-oesophageal reflux was demonstrated in only one of six patients studied. Oesophageal manometry shows a small high pressure zone in all of six patients studied. Other workers have reported partial wrap fundoplication, but in all cases they have covered the exposed mucosa with gastric fundus[13,14]. Our procedure combines the benefits of a partial wrap fundoplication with a means of preventing reunion of the myotomy and obviates the need to excise a strip of oesophageal muscle. It is simple and avoids the necessity of thoracotomy and the not insignificant incidence of post-thoracotomy pain. To our knowledge, this technique has not been reported before.

Angelchik prosthesis

Sir

We were very alarmed to see a report about a patient undergoing oesophagogastrectomy for the removal of an Angelchik prosthesis that had eroded into the lower oesophagus (*Br J Surg* 1988; **75**: 826).

We feel that this was an unnecessarily drastic way of treating this particular complication. We have recently had a very similar case. A 65-year-old man developed sudden onset of dysphagia 56 months after the insertion of an Angelchik prosthesis. On endoscopy the prosthesis could be seen lying in the lumen at the junction between the oesophagus and stomach. At subsequent laparotomy it was impossible to feel the Angelchik prosthesis via the abdominal approach as the prosthesis had ridden up above the diaphragm. There were marked adhesions around the lower oesophagus. A gastrotomy was made and on inserting a finger into the stomach and up into the lower oesophagus the prosthesis could be easily palpated. The prosthesis was pulled down into the abdominal cavity. A small cut down was made through the oesophageal wall on to the knot of the tapes. The tapes were thus divided and as soon as the tapes had been cut the prosthesis was easily removed. The small hole in the oesophagus was closed with interrupted silk sutures. The gastrotomy was also closed. The patient had an uneventful postoperative course, being discharged home on the fifth postoperative day. He has remained asymptomatic since. This clearly is a much simpler and safer way of removing the prosthesis and we would find it very hard to justify a resection in a benign condition.

Gallbladder non-filling at ERCP

Sir

Worthley and Toouli's finding (*Br J Surg* 1988; **75**: 796–8) that six of their eight patients with non-filling of the gallbladder at endoscopic retrograde cholangiopancreatography (ERCP) developed acute gallbladder problems after endoscopic sphincterotomy leading to death in three is of interest and concern. However, their conclusion that non-filling of the gallbladder indicates the need for cholecystectomy is contrary to the experience of ourselves[1] and others[2] who have studied many more patients. Worthley and Toouli state that our lack of effort to fill the gallbladder at ERCP limits the conclusions which can be drawn. The majority of our patients undergoing surgery after sphincterotomy had gallbladder filling at ERCP and it is difficult to understand how more strenuous efforts to fill the gallbladder on our behalf would have altered our conclusion that gallbladder non-filling is not a useful predictor of future problems.

Worthley and Toouli state that 17 of our patients required cholecystectomy for gallbladder problems. Careful reading of our paper shows that this is wrong. Eight patients underwent cholecystectomy and exploration of the common duct because of failure of endoscopic clearance not because of gallbladder symptoms. Two other patients had failed endoscopic duct clearance but were unfit for operation. Five patients underwent elective cholecystectomy after common duct clearance because their referring surgeons considered this an appropriate course of action not because of gallbladder symptoms. Only four of the remaining 65 patients required cholecystectomy for persisting symptoms and in three of these the gallbladder had filled at ERCP.

Our indications for cholecystectomy after sphincterotomy were the persistence or appearance of symptoms related to the gallbladder or failure to clear the common duct. The same criteria applied to Worthley and Toouli's study shows that, of their 12 patients in whom the gallbladder filled, two required early cholecystectomy for symptoms and two others had residual common duct stones. Thus four of 12 patients in whom the gallbladder had filled required cholecystectomy. Of their eight patients in whom the gallbladder did not fill, one had residual common duct stones and six required cholecystectomy for recurrent symptoms although one of these six patients actually required surgery for cholangitis associated with stenosis of the sphincterotomy rather than a primary gallbladder problem. Thus cholecystectomy was actually indicated in six. Worthley and Toouli have applied different criteria in their assessment of their study and ours. Applying the same criteria to both studies indicates that their data do not support their contention that gallbladder non-filling is an indication for cholecystectomy. This remains true even if we take the sensible step of excluding from analysis those patients with failed endoscopic clearance.

This matter is clearly not resolved and further long-term studies are necessary to evaluate predictors of the future development of complications. Our advice to surgical colleagues managing patients in whom they have cleared the common duct of stones but in whom the gallbladder remains in position is that acute gallbladder problems requiring surgery are not common and that elderly and high-risk patients are far more likely to die from non-biliary disease. Worthley and Toouli's paper fuels the fire for continued evaluation of these patients but has not demonstrated that patients with non-filling of the gallbladder should proceed to cholecystectomy.

Authors' reply

Sir,

The number of patients in our series is relatively small when compared with other series. However, appropriate statistical analyses were applied and the differences are as reported. We have applied a Fisher's extact test after excluding those with failed endoscopic clearance and sphincterotomy stenosis as suggested by Drs Martin and Tweedle, and again show a significant difference $P < 0.05$. Therefore our conclusion remains as stated in the manuscript, i.e. 'should the gallbladder fail to opacify despite free cannulation of the common bile duct, dense opacification of the extrahepatic biliary tree and filling of the tertiary intrahepatic bile ducts, then cholecystectomy is recommended to avoid future gallbladder problems'. We are reluctant to veer from this recommendation at our institution in the light of the results which we have reported in the manuscript. The fact that some patients with a patent cystic duct also need cholecystectomy does not refute the findings of our study. However, we agree with Drs Martin and Tweedle's comments that evaluation of these patients must continue in other centres in order to either support or refute our conclusions. Our only plea is that researchers conducting these studies ensure that close follow up is undertaken in order to confirm that reported deaths from non-biliary disorders are indeed accurate. It is not uncommon for cholecystitis to aggravate cardiac disease in elderly patients leading to the cause of death being labelled as non-biliary.

Postoperative wound pain

Sir

We read with interest the paper by Gibbs *et al.* (*Br J Surg* 1988; **75**: 923–4) on continuous wound perfusion with bupivacaine for postoperative wound pain which reported results at variance with many published studies.

Intercostal nerve block has been found to be effective not only in producing postoperative analgesia but also in improving pulmonary function after cholecystectomy[1]. It has also been found to be beneficial after appendicectomy[2]. We have been using continuous extrapleural infusion of bupivacaine via a catheter placed at thoracotomy after thoracic and upper abdominal procedures and we have found this method to be valuable in reducing the requirement for postoperative narcotic analgesics and also in improving forced expiratory volume in 1 s (FEV_1), forced vital capacity (FEC) and peak expiratory flow rate[3].

The mechanism of action of intercostal nerve block administered extrapleurally depends not only on spread of the local anaesthetic agent longitudinally along the intercostal spaces but perhaps more importantly via paravertebral spread medially which would result in more extensive blockade[4]. This emphasizes the importance of applying the blockade at the angle of the rib concerned. Effective nerve blockade is unlikely to be achieved when the local anaesthetic agent is applied as anteriorly as that used by Gibbs *et al.* with paramedian incisions. Their results confirmed this. Furthermore, by placing the catheters between the peritoneum and the rectus muscle not only would wound infiltration be lost by leakage through the previously opened peritoneum and impeded by the rectus muscle, but also by the fact that the majority of the sensory branches of the intercostal nerves supplying the anterior abdominal wall would have become superficial to the rectus muscle at a paramedian position[5].

We believe that by modifying the technique of the infusion, the authors would have detected significant benefits from the use of continuous perfusion of bupivacaine.

'Sculpted' T tubes

Sir

In his recent correspondence, Mr Dawson (*Br J Surg* 1988; **75**: 932) describes a clinically significant bile leak following removal of a 'sculpted' T tube on the tenth postoperative day after choledocholithotomy. He concludes that the shape of the T tube is unlikely to be the critical factor for this problem.

As a proponent of the 'sculpted' T tube I have previously emphasized the need to avoid using plain or chromic cat-gut to close the common bile duct around the T tube[1]. Chromic cat-gut loses two-thirds of its tensile strength within 10–15 days, and sooner in the presence of infection which is almost invariable in choledocholithiasis. For this reason, interrupted sutures such as Vicryl® or PDS which are relatively slowly absorbed should be used.

Furthermore, after a normal postoperative T tube cholangiogram, it is useful to clamp the T tube for 24 h before actual removal. The development of symptoms following this may presage a potential leak and therefore prompt delayed removal of the T tube.

In a recent series of 223 T tubes inserted after common bile duct exploration there were five significant leaks following their removal[2]. All these had been dislodged or removed before 10 days and in no case had a 'sculpted' T tube been used; in all cases chromic cat-gut had been used to close the common bile duct. In two situations where I re-opened such patients for this problem the striking finding was a disrupted bile duct at the site of the T tube, associated with partial dissolution of the cat-gut. Using the above described techniques in my own, albeit limited, experience I have yet to experience a significant intraperitoneal bile leak.

Before accepting Mr Dawson's suggestion about the shape of the T tube as not being of major importance, can he reassure us that in the case he described he had used sutures other than cat-gut and had employed clamping before removal?

Author's reply

Sir

In answer to the points raised by Mr Neoptolemos:

1. After the T tube cholangiogram was done on the seventh postoperative day, the T tube was clamped on the eighth postoperative day and remained so until the tenth postoperative day when it was removed. The patient was perfectly well during this time.
2. At operation (by me) the opening in the duct was the size of the side arm of the T tube. There was no evidence of disruption of the suture line, indeed the duct had to be incised to allow insertion of a further T tube.
3. The duct was closed with interrupted 3/0 chromic cat-gut sutures. (I use this material for biliary duct closure and anastomoses.)
4. The most significant operative finding was the total lack of any track formation around the T tube. I believe this to be the most important factor in producing this complication.

Your readers may recall that some 25 years ago plastic transparent non-irritant T tubes were introduced for a while. The incidence of biliary peritonitis following their removal was extremely high. The non-irritant plastic produced no peritoneal reaction at all.

Diagnosis and management of graft–enteric fistulae

Sir

Dr Tilanus and colleagues (*Br J Surg* 1988; **75**: 915–6) show once again how deadly this complication can be, and that graft excision and axillofemoral bypass are not the perfect answer. For a good many years a few of us have made a plea for a more conservative approach in selected cases. In 1982[1] I published the results of direct repair in 11 of my patients, the first three of whom were operated on far away from St. Mary's by the surgeon on emergency call. It was the survival of these three, and of four others who I learned about while in New Zealand in 1975, that made me try for myself to see if such results could be reproduced. By 1982 there were eight cases, with one death from erosive gastritis, the repair being intact, two patients with early infective fistulae in whom the method was, in retrospect, inappropriate, and four patients who recovered. My second such patient, a man aged 72 years, is still alive and well 11 years after direct repair of a clean false aneurysm that was leaking into the duodenum. The fifth case was operated on by one of my ex-senior registrars; the patient re-bled fatally from an unknown source soon after the repair.

Three other patients have recovered after direct repair by my colleague Miss Averil Mansfield, FRCS. When these eleven patients were reviewed recently by Mr Michael Grigg, FRACS (unpublished results), he found that, at a mean follow-up interval of 48 months, seven were alive after simple direct suture.

I was particularly pleased that our British colleagues have published their results in the Journal, having heard their paper at an earlier stage at our Second International Vascular Symposium in London in 1986.

Small bowel obstruction

Sir,

In regard to the case reported by Huddy and Bailey, 'Small bowel obstruction due to peritoneal encapsulation' (*Br J Surg* 1988; **75**: 262), we should like to raise some points related to the technical approach which should be kept in mind during release of such an encapsulation.

Peritoneal encapsulation, also called 'internal omphalocele'[1], is characterized by location of the small bowel behind an accessory peritoneal avascular membrane. The enclosed intestines are not necessarily normal, as stated by Huddy and Bailey, but may also be malrotated[1].

Left paraduodenal hernia is a possibility which should be considered in the differential diagnosis at laparotomy. This hernia, first described by Landzert[2] in 1871, develops in the left paraduodenal fossa and is located to the left of the fourth portion of the duodenum. It is frequently seen in the fetus and newborn and has been reported to be present in 2 per cent of autopsied bodies[3]. This fossa develops in the embryo by the elevation of a peritoneal fold by the 'vascular ring of Treitz', which is formed by the inferior mesenteric vein from above and the ascending branch of the left colic artery from below[4]. Since the 'neck' of this 'sack' contains the above-noted vascular elements, it is advisable that reduction be attempted without opening of the sack. If this is not possible the sack should be opened through its anterior wall and its contents reduced by compression from within and external traction. After reduction is completed the free edge of the sack should carefully be examined, to be divided only if no vascular structure is observed.

Otherwise, as recommended by Davis[5], the posterior peritoneum should then be incised on the left up to the duodenal–jejunal junction and the neck of the sack, containing the inferior mesenteric vein, buried in this bed, restoring its normal retroperitoneal position.

Opening of the sack by dividing the 'thickened neck', as reported by Huddy and Bailey, involves the potential risk of vascular damage and is therefore not the recommended sequence of this surgical procedure, except when the neck is clearly avascular.

Since peritoneal encapsulation and left paraduodenal hernia are both avascular membranes in a similar location, differential diagnosis should be considered. By pointing out these anatomicosurgical concepts, we hope to enhance the value of the reported case for the readers of your prestigious journal.

Authors' reply

Sir,

Thank you for the opportunity to reply to the letter from Drs Freud and Zer. We agree entirely with the points that they make and with the necessity to distinguish between peritoneal encapsulation and left paraduodenal hernia.

The operation which they describe is a safe approach. However, in those cases where the inferior mesenteric vein can be seen not to run in the neck of the sac, division of the constricting band will allow release of the obstructed small bowel without the trauma of traction or compression. As with any surgical procedure no structure should be divided until it can be identified.

'Loop mattress suture'

Sir

The mattress suture, which has a deep bite, is useful for the elimination of dead space under a wound and provides excellent apposition of the edges of the wound. We have successfully used this method of stitching mattress sutures in many types of plastic reconstructive surgery during the past 10 years. Dr Condon described his method in 1968, and Dr Gault reported a similar method in 1987 within the pages of this Journal. In each case, removal of stitches is accomplished by incising the loop of the knot.

In our method (*Figure 1a*), we feature a long loop which is easily severed, enabling smooth removal of the suture by applying slight traction. In Gault's method (*Figure 1b*), there is the possibility of a suture being severed at a point other than the quite short loop, thereby hampering easy removal of a suture.

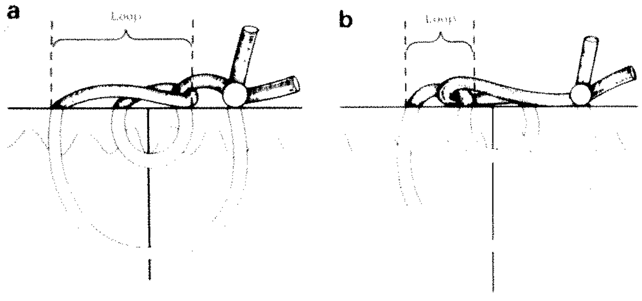

Figure 1 *The length of the loop* **a** *in our method, as compared with* **b** *Dr Gault's method*

Review of a hospital experience of breast abscesses

Sir

We would like to add our experience to that of P. K. H. Tam and H. Brooks (*Br J Surg* 1988; **75**: 190) who make a plea for the treatment of breast abscesses by needle aspiration as an alternative to incision and drainage.

The original article by J. H. Scholefield, J. L. Duncan and K. Rogers[1] (*Br J Surg* 1987; **74**: 469–70) pointed out that the majority of such abscesses in practice today are due to duct ectasia, and the infective organisms, if any, are anaerobic.

At our breast clinic we have seen a large number of such cases and it is our practice to treat them by needle aspiration and bacteriological examination, followed by suitable antibiotic therapy. In many the 'abscess' is a sterile inflammatory reaction to the inspissated material in the ducts which has leaked into periductal tissue. Breast ultrasound has shown itself to be a very useful way of confirming diagnosis, and surgical incision has not been necessary.

We would agree with Scholefield, Duncan and Rogers that if any surgical treatment is necessary, a major excision of the duct system (Hadfield's operation) is the treatment of choice. It is much better, however, to carry out this procedure when any sepsis has resolved.

The surgical scarring which is produced by conventional incision and drainage of breast abscesses is very unsightly and in our opinion unnecessary in most cases.

Femorodistal graft stenoses

Sir,

We read with interest the paper by Grigg *et al.* on femorodistal graft stenoses (*Br J Surg* 1988; **75**: 737–40). Our experience with Duplex scanning has been similar[1,2]. We would certainly agree that measurements of flow rates show a great deal of variation and have limited application in graft surveillance[3].

One of the repeated criticisms we have faced in the past is that scanning a whole graft must be a lengthy procedure. With experience we have found this not to be the case and new developments, e.g. colour coded Doppler flow, make more rapid scanning feasible. As Grigg *et al.* suggest a 6-weekly surveillance in the first 6 months we are sure they agree with us on this point. The distal anastomosis can be difficult to assess in femoropopliteal grafts. Where the distal anastomosis is to a crural vessel, then assessment is much easier. It would be interesting to know the difficulties Grigg *et al.* experienced with this technique. We feel it is also worth pointing out that Duplex scanning can be used to assess all types of grafts as others have found[4].

We would also support the suggestion that thrombogenicity must be a source of some graft failures. In our prospective study five out of six grafts which occluded without warning were prosthetic.

Documenting these facts objectively and non-invasively will increase our understanding of the causes of graft failure and help prevent it.

This important paper adds to our own reports on the usefulness of Duplex scanning in graft assessment and provides a simple objective criterion for categorizing graft stenoses which we shall certainly adopt.

Author's reply

Sir

McShane and Chant are generous in their comments on our paper and we are grateful. Many units in both Europe and the USA have used Duplex for graft follow-up with varying success. Firstly, the technique can be time consuming and we agree that technical developments have improved this, but it remains imperative to assess the whole graft rather than sampling it, as velocities and flow may return to normal downstream from a stenosis. Secondly, as they point out, the distal anastomosis can be difficult to assess. We sought to overcome this problem by assessing the graft just proximal to the anastomosis and the popliteal artery just distal to it. This problem only arises in femoropopliteal grafts as anastomoses to crural vessels at the level of the ankle are easier to assess. However, in these patients the small distal vessels may be difficult to pick up.

Many aspects in the postoperative use of Duplex scanning were not mentioned in our paper, and we apologize if this confused the reader. The single purpose of our communication was to publish a reproducible formula that should simplify our objective assessment—particularly in the assessment of early, non-haemodynamically significant stenoses.

Body wall ecchymosis

Sir,

We read with interest the paper by Wilson on body wall ecchymosis in acute pancreatitis (*Br J Surg* 1988; **75**: 704). We would like to draw attention to another previously unreported differential diagnosis of abnormal wall bruising.

Case report

A 58-year-old man presented with a 2-day history of vomiting, crampy colicky abdominal pain and constipation. There was no previous history of abdominal surgery. On examination there was an area of discoloration periumbilically. Apart from a possible paraumbilical mass with a cough impulse no other physical signs were elicited.

At operation, a periumbilical hernia with a small neck of viable small intestine and strangulated fat was found. The fat and hernial sac were excised, the peritoneum was closed and the defect repaired. The patient made an uneventful recovery.

Cullen's sign was originally described as a feature of acute haemorrhagic pancreatitis (Grey Turner's sign is discoloration in the flanks, whilst Cullen's sign is in the anterior abdomen). Cullen-like coloration has been reported in ruptured abdominal aortic aneurysm, ruptured ectopic pregnancy and mesenteric infarction. The present case illustrates this sign in strangulated paraumbilical hernia. The mechanism is uncertain but may involve necrosis of tissue producing local skin inflammation. Awareness of this sign may help in the differential diagnosis of all the above conditions.

Incisional hernias

Sir,

In the surgical workshop section (*Br J Surg* 1988; **75**: 689) an operation is described for incisional hernia. It is unattributed and unreferenced suggesting that it is a novel concept and technique which it is not. Ton[1] in 1967, Boerema[2] in 1971 and subsequently others[3] have described in full the concept and detailed description of this operation. The definition of patients who are suitable is not discussed; small and moderate incisional hernias do not require this operation, only those which are 10 cm or more in diameter. The notion expressed that only those who have dieted successfully should be considered denies the realities of the clinical situation. These large incapacitating hernias often occur in exactly the obese middle aged patients who are quite unable to reduce weight by any means as their energy expenditure is so limited by pain and hernial size. The technique described leaves much to be criticized: the peritoneum, contrary to the advice given, must be opened to free large areas of omental attachments; the use of material as pliable as Redivac® drains (O.E.C. Orthopaedic) (even 'large') is inadvisable; 6 mm Teflon® (Du Pont, UK) rods with predrilled holes every 2 cm are far preferable. The emergence of these tubes from the skin exposes the patient to the risk of infection. In a series of 38 Boerema type repairs done by ourselves and Mr A. B. Birt and colleagues from Norfolk, wound infection was the most serious complication despite complete skin coverage and antibiotic prophylaxis. Certainly the use of nylon does not 'eliminate' infection.

This description is imprecise, wrong in important details, lacking in long-term follow up in any significant numbers and inadequate in its indications.

Parotid tumours

Sir

Mr Maynard draws attention to an important point in the diagnosis and misdiagnosis of parotid tumours in his article (*Br J Surg* 1988; **75**: 764–6). There is substantial documentation that the treatment of choice with the lowest recurrence rate for pleomorphic adenomas is complete extracapsular excision after exposure of the facial nerve trunk and branches. However, in dealing with benign parotid tumours such as adenolymphoma, and especially enlarged lymph nodes, enucleation is an appropriate treatment.

We have previously reported[1] the need for the precise diagnosis of the nature of parotid tumours to avoid just the problem which Mr Maynard raises. In all masses in the lateral neck in the vicinity of the parotid and especially in those laying beneath the angle of the jaw in the situation commonly occupied by enlarged jugulodigastric lymph nodes, two investigations will provide certain diagnosis in virtually every case. Firstly, a fine needle aspiration biopsy will identify pleomorphic adenoma in 100 per cent of cases and adenolymphoma in 60–70 per cent[1,2]. Secondly, CT scan will demonstrate the parotid gland and the position of the occupying tumour with precision. In the event of an outlying or separated tumour mass, the fine needle method will have established its nature.

The use of these tests will help reduce or eliminate the problem of inadequate parotid tumour operations on the one hand and on the other permit less hazardous enucleation for those masses which only need this form of removal.

Book reviews

A Colour Atlas of AIDS and HIV Disease

C. F. Farthing, S. E. Brown, R. C. D. Staughton. Pp. 113. Illustrated. 1988. London: Wolfe Medical Publications. £16.00.

I have found this a most informative book. The book first reviews the history and epidemiology of the AIDS epidemic. The virology and immunology are next described, and antibody tests and the clinical response to HIV are explained. These explanations are particularly recommended as they are lucid and comprehensive.

The clinical manifestations of AIDS are well illustrated by colour photographs and there is a most useful chapter on counselling.

This book can be confidently recommended to the practising doctor, be he in hospital or community practice. The book is coherent and comprehensive, well illustrated and without typographical or other editorial mistakes.

Laparoscopy

J. W. Saleh. 178 × 267 mm. Pp. 265. Illustrated. 1988. Philadelphia: W. B. Saunders. £44.00.

It is difficult to be sure for whom this book is intended. The title suggests that all aspects of laparoscopy will be discussed fully but gynaecologists and general surgeons are likely to be disappointed for the author's declared interest in hepatology makes this effectively a textbook of medicine. Only two chapters deal with emergency and gynaecological laparoscopy.

Although well written and presented, not enough space is allowed to explore the more challenging use of the laparoscope in the acute abdomen. There is no mention of the 4 mm mini-laparoscope recently developed by Stortz for use in blunt injuries of the abdomen. Also, sadly, not enough is made of the value of laparoscopy in the differential diagnosis of lower abdominal pain, particularly that between appendicitis and gynaecological causes of pain where inappropriate surgery may have an adverse effect on the reproductive potential of the young woman treated.

The emphasis on a local rather than a general anaesthetic approach again displays the author's medical background, but a hint of the therapeutic value of laparoscopy in the hands of the physician is well described in the division of adhesions, particularly in the Fitz-Hugh–Curtis syndrome — a condition undergoing a revival at the present time. The technical aspects of laparoscopy are well described with excellent line drawings and colour photographs. The section on gynaecological laparoscopy is particularly good, giving some idea of the potential of this instrument in surgery in the future.

Despite a seemingly critical review this is a very readable book but, for the surgeon, it will inevitably remain a reference book only.

B. F. Ribeiro

Consultant Surgeon
Orsett Hospital
Grays
UK

Atlas of General Thoracic Surgery

M. M. Ravitch. 218 × 282 mm. Pp. 413. Illustrated. 1988. London: Academic Press. £77.95.

The authors are internationally known thoracic surgeons. As they readily accept, the book owes much to the work of an outstanding medical illustrator and it is perhaps a little surprising that he is not included as an author. The book is 413 pages long and contains a comprehensive index. There are nine sections covering anatomy, chest wall operations, the diaphragm, thoracic incisions, the thoracic skeleton, diagnostic and therapeutic procedures, pulmonary resections, trachea and oesophagus. Most sections cover several operations and alternatives are proposed. The choice of operations is comprehensive. Over 30 excellent coloured plates are used to illustrate normal anatomy in several sections of the book. Over 100 operations and procedures are described with line drawings and black-and-white shaded plates. Each procedure is accompanied by a small number of key references. As acknowledged by the authors, many of the drawings have already been used elsewhere. Whilst this is reasonable economy, these are often combined with line drawings which are sketchy and the lack of uniformity within a subject leads to confusion. Some of the line drawings are complex and colour would have been preferable. The section on the chest wall is perhaps too extensive, being 77 pages in length, but this is understandable given the special interest in this subject by some of the authors. The section on thoracic incisions inevitably displays an individual approach and, whilst one must respect the experience of the authors, most thoracic surgeons in this country would not now resect the back-end of the ribs in an uncomplicated thoracotomy. The section on diagnostic procedures covers simple undertakings such as needle biopsy and intercostal drainage. The section on mediastinoscopy is not well illustrated and colour would have been preferable. One must take issue with the routine resection of costal cartilage when undertaking anterior median sternotomy. The sections on pulmonary resection and oesophageal disease are thorough but throughout there seems to be an undue emphasis on stapling techniques. Surely, even in the United States there are surgeons who still prefer suture techniques and I found this overemphasis irritating. The section on the trachea is written by Dr Grillo, a renowned expert in this field. Unfortunately too few illustrations are used and these complex operations are therefore understandable only to those experienced in this specialized field.

It is difficult to appreciate the market intended for this book. It is perhaps a tribute to the illustrator that some of the operations are made to look easy, especially those in pulmonary resection. Many of the key early steps in such operations are omitted and the illustrations may encourage the inexperienced to attempt surgery which would be beyond their ability. This book is very definitely for the experienced thoracic surgeon or those advanced in their training, and therefore the inclusion of intercostal drainage and thoracic incisions would appear unnecessary. This book provides no substitute for formal training and apprenticeship but is an excellent supplement and will find its way deservedly into the reference libraries of those institutions concerned with thoracic training.

Otolaryngology: Head and Neck Surgery

D. D. Weese, W. H. Saunders, A. J. Schleuning. 267 × 168 mm. Pp. 600. Illustrated. 1988. St. Louis, Missouri: C. V. Mosby Co.

This seventh edition of a standard North American text is aimed primarily at resident training programmes but also at medical students, nurses and dentists. The authors have attempted to encompass the whole of the speciality of otolaryngology, head and neck surgery, including audiology, reconstructive and facial cosmetic surgery, into one volume of just under 600 pages. The use of a rather long-winded discoursive style has made this objective almost unattainable. Although the management of the various regions such as the larynx and hypopharynx follows a set pattern with anatomical descriptions followed by physiology and embryology, the constraints of space have made it impossible to present, for example, physiology in an adequate way which might satisfy the examiners in the Board examinations or The Royal College of Surgeons. Although several of the chapters are excellent and cover the field adequately — particularly salivary gland disease and dizziness and vertigo — I am afraid that there is a lack of direction and commitment in several others. The chapter on sinus disease omits any mention of sinoscopy or functional endoscopic surgery and the discussion of sinus malignancies is incomplete and misses out the ethmoid sinuses and developments in cranial facial surgery completely.

Although this book is nicely produced and well illustrated, as it stands it would not provide an adequate fund of knowledge to ensure a pass in the specialist examinations in the UK.

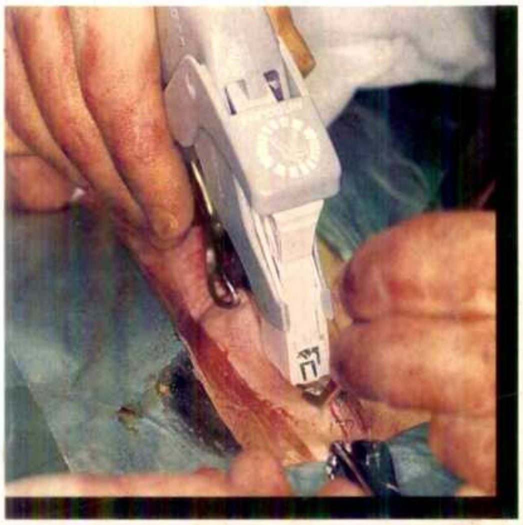
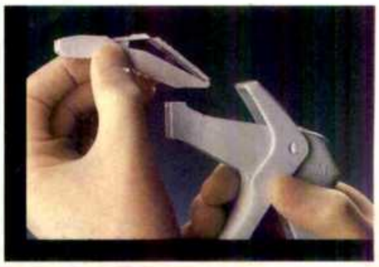
The 'Precise' skin stapling system



Each **Precise** stapler can be loaded, magazine style, into a handle.



Stapling is four times faster than skin suturing.[1] Patients spend upto 33 minutes less on the operation table.[2] Poor risk patients can spend less time under anaesthetic.[2,3,4] Better cosmetic results and lower infection rates are possible.[5,6] **Precise** skin staplers have been shown to be cost effective.[1]

Precise skin staplers operate in one smooth, fast action.

Significant savings include:

Freeing of theatre time.[2]
Conservance of expensive anaesthetic agents.
Lower materials wastage.
Reduction in the incidence of infection.
Less use of antibiotics.
More efficient use of beds for in-patient cases.
These are compelling reasons for choosing **Precise** skin staplers.

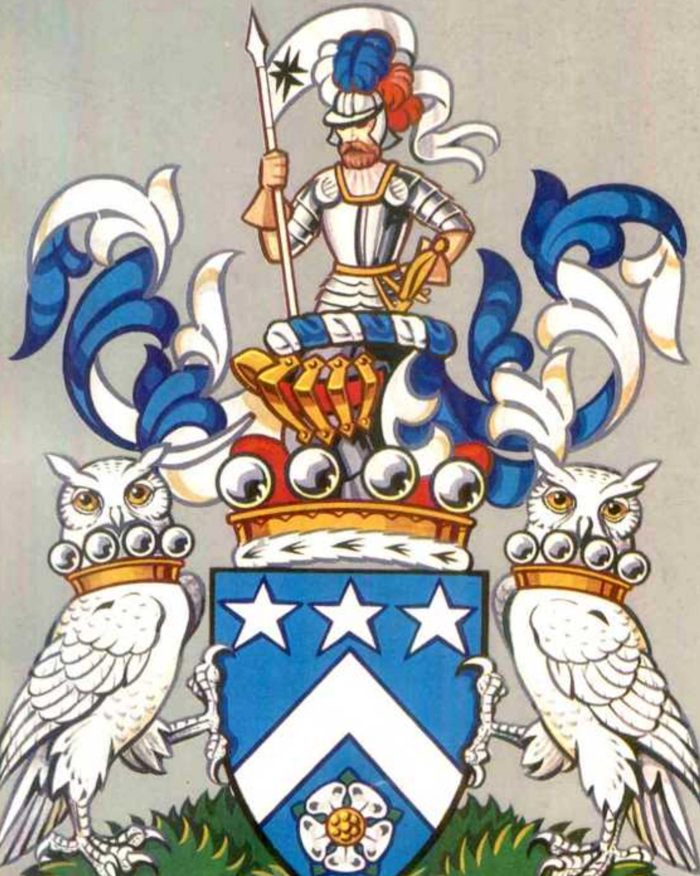
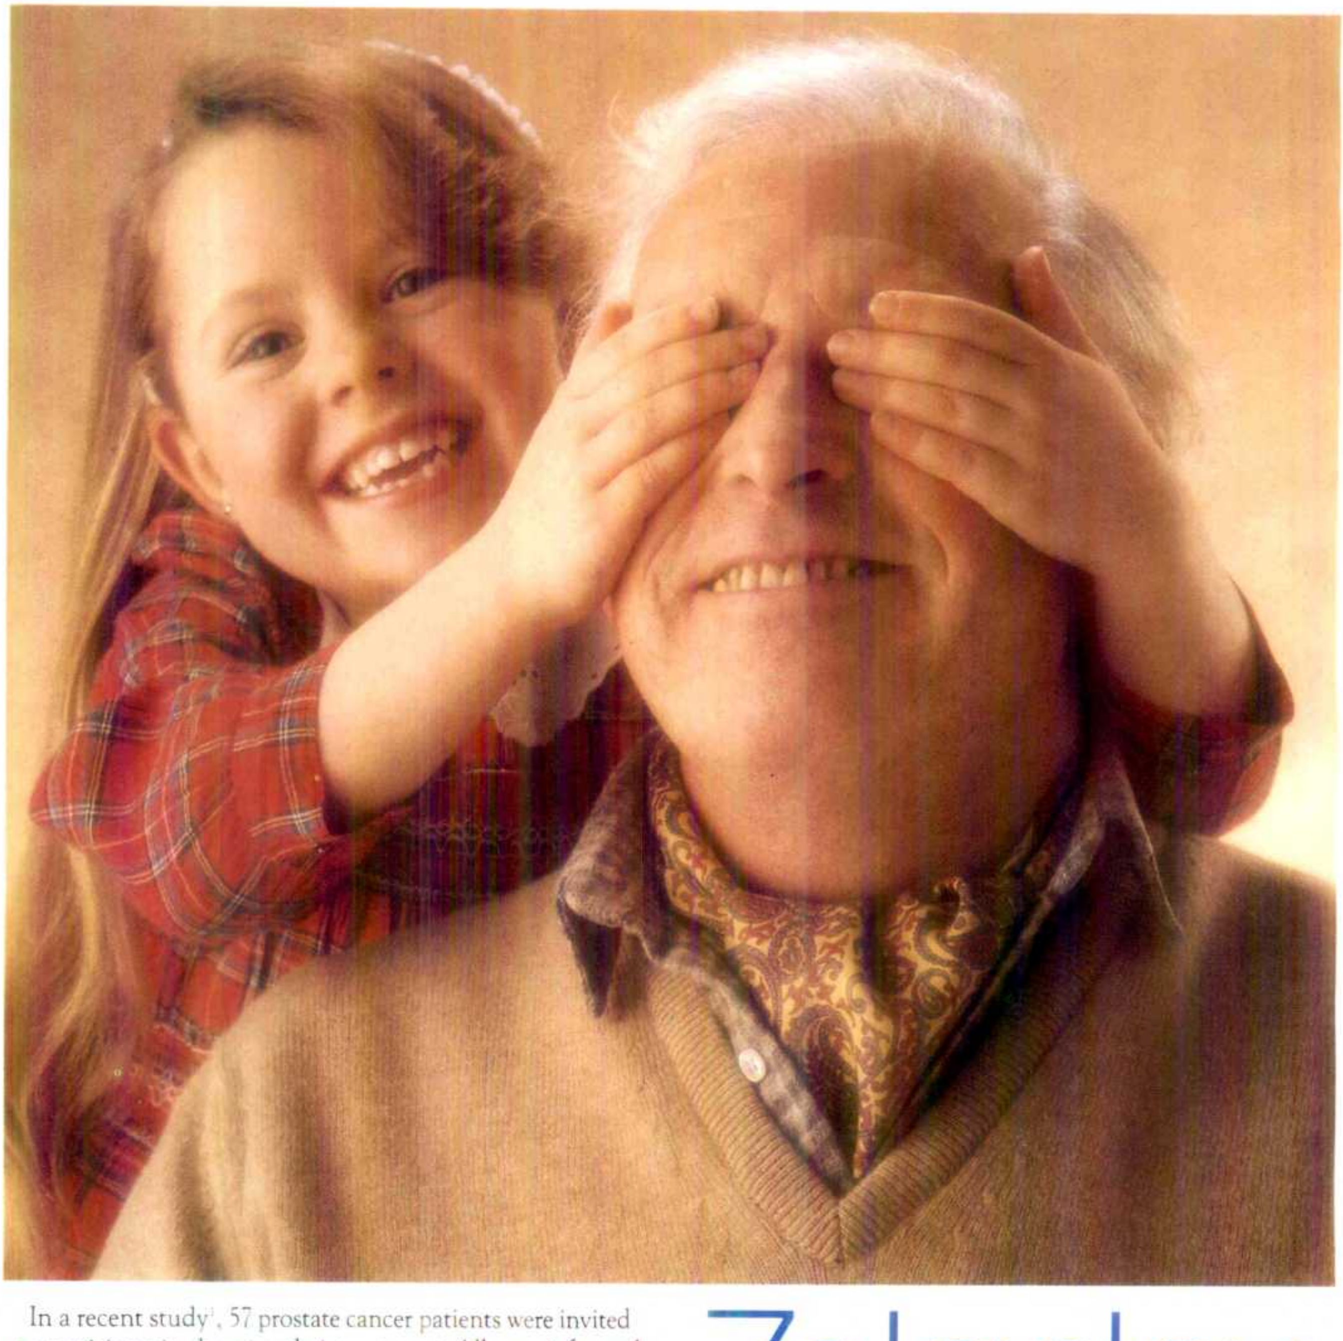
Volume 76, Number 2, February 1989



Guess which prostate cancer treatment most patients would choose.



In a recent study[1], 57 prostate cancer patients were invited to participate in choosing their treatment. All were informed that the two treatments available, sub-capsular orchidectomy or 'Zoladex', were similar in efficacy and side effects. 49 of the patients (86%) opted for 'Zoladex'.

A recent trial[2] has established the equivalence of 'Zoladex' to orchidectomy.

Zoladex

goserelin

Effective therapy without surgery.

▼ 'ZOLADEX' PRESCRIBING NOTES.

Use: Prostate cancer suitable for hormonal manipulation. **Presentation:** A sterile depot containing goserelin 3.6mg. **Dosage and administration:** One depot injected subcutaneously into the anterior abdominal wall every 28 days. **Precautions:** Care with patients at particular risk of developing ureteric obstruction or spinal cord compression. Consider initial use of an anti-androgen at the start of therapy. **Side effects:** Hot flushes, decrease in libido and occasional breast swelling and tenderness. Skin rashes (generally mild). Occasional mild bruising at injection site. Initial transient increase in serum testosterone may cause temporary increase in bone pain. **Product licence number:** 29/0198. **Basic NHS Price:** £114.00 per depot. 'Zoladex' is a trademark. Further information is available from: ICI Pharmaceuticals (UK), Southbank, Alderley Park, Macclesfield, Cheshire SK10 4TF.

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer-Verlag 1981: 123–63.

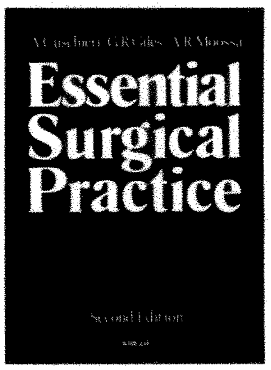
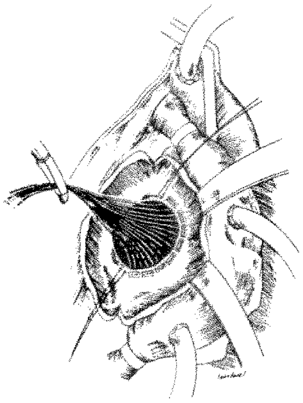
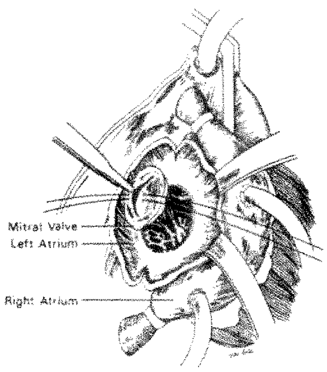
Essential Surgical Practice
Second Edition

Edited by
A Cuschieri MD ChM FRCS(Eng) FRCS(Edin)
Professor and Head of Department of Surgery, University of Dundee, Ninewells Hospital, Dundee, UK
G R Giles MD FRCS
Professor and Head of Department of Surgery, St James's University Hospital, Leeds, UK
A R Moossa MD FRCS(Eng) FRCS(Edin) FACS
Professor of Surgery and Chairman of the Department of Surgery, University of California, San Diego; Surgeon-in-chief, University of California Medical Center, San Diego, California, USA







★ Second edition of this classic systematic and comprehensive surgical textbook ★ Thoroughly revised and completely up-to-date ★ The section on cardiac surgery has been rewritten and to reflect its increasing importance there is a completely new section on the specialty of trauma surgery ★ Over 100 new illustrations ★ Comprehensively indexed ★ Many references for further reading

The second edition of this classic surgical textbook for postgraduate students has been thoroughly revised and updated to reflect the most recent advances and developments. The cardiac surgery section has been completely rewritten under new authorship and there is an entirely new section on trauma, rapidly emerging as a separate surgical specialty. All other chapters have been extensively revised or rewritten to bring them completely up-to-date.

Reviews of the First Edition

'This book is highly readable and is a real contribution to surgical education.' *Archives of Surgery*

'It should be a great success on both sides of the Atlantic.' *Annals of the Royal College of Surgeons*

'. . . Covers very well an extensive range of material which is well illustrated and readily comprehensive. It should be very useful equipment for the trainee surgeon for the Australasian college.'
New Zealand Medical Journal

Concise Contents: General surgical aspects ● Trauma ● Head and neck surgery ● Neurosurgery ● Thoracic surgery ● Cardiac surgery ● Vascular surgery ● General surgery ● Genito-urinary surgery

April 1988 1456 pages 272 x 210mm Hardcover Illustrated – 604 line and 891 halftones

EXECUTIVE DIRECTOR R N THOMSON, M A

Section of COLOPROCTOLOGY

A NOTICE OF INTEREST TO ALL DOCTORS INVOLVED IN COLOPROCTOLOGY

The Officers of the Royal Society of Medicine have been sent a request by Members and Council of the Section of Coloproctology that their Section be renamed:

THE BRITISH ASSOCIATION OF COLOPROCTOLOGY
(at The Royal Society of Medicine)

In order to fulfil the functions and duties of such an Association it would be necessary for the Section to cater more widely for proctologists who do not find it easy to travel to London. To meet this need it is hoped to set up a series of Regional "Chapters" based upon existing coloproctology societies and groups and providing representation for such groups on the Council. It is also hoped to build on the Section's current policy of holding out of town meetings in regional centres in Scotland, Wales, the North of England and Northern Ireland.

The Council feel it important that the views of coloproctologists throughout the country should be sought regarding the above proposals. I would therefore be grateful if you would write to me so that I can pass your own views on th appropriate Council meeting – letters please to reach me within a month of publication of this Journal.

Even if you do not wish to modify the above suggestions but are essentially in support of them a letter indicating this view would be much appreciated.

R. J. Heald, M. Chir *Honorary Secretary – Section of Coloproctology*

REPRINTS

Reprints of all articles in this journal are available in quantities of 100 or more.

Reprints are essential —

- for the company that wants to distribute impartial comment on its activities to potential customers and clients
- for the company that wants to up-date its technical staff on new techniques and new technologies

KING'S COLLEGE HOSPITAL
F.R.C.S. Revision Course
in
CLINICAL SURGERY
April 3rd – 14th, 1989

An intensive revision course designed for final FRCS candidates will be held at King's College Hospital over a period of 2 weeks. All major specialties will be covered as well as Oncology, Vascular, Urological, Hepato-Biliary and Orthopaedic surgery. Sessions on radiology, surgical pathology, operative surgery and clinical examination techniques are included. Lectures by visiting experts will be a feature of the course. Places will be limited and early application is advised.

Local accommodation can be arranged.

Application closing date – 13th March, 1989.

Course Fee: £260

Further details and application forms from:

Mrs J Reeley
Dept of Surgery
Rayne Institute

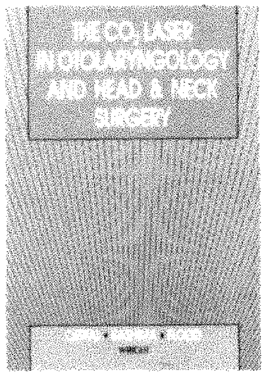
The CO_2 Laser in Otolaryngology and Head and Neck Surgery



Editors:

V H Oswal FRCS, DLO
Consultant ENT Surgeon, North Riding Infirmary, Middlesbrough, Cleveland, UK

H K Kashima MD
Professsor, Department of Otolaryngology–Head and Neck Surgery, The Johns Hopkins Medical Institutions, Baltimore, Maryland, USA

L M Flood FRCS
Consultant ENT Surgeon, North Riding Infirmary, Middlesbrough, Cleveland, UK

- ★ **written by an international team of experts in laser usage**
- ★ **defines the place of the CO_2 Laser in the management of ENT, Oral and Tracheobronchial Lesions**
- ★ **extensively illustrated with high quality line drawings and half tone illustrations**

The CO_2 laser has rapidly established itself as a valuable tool for the otolaryngologist and head and neck surgeon. It has clear advantages over conventional methods of surgery and its use will continue to grow. For all those who need to learn more about laser techniques in these specialties, this book will provide an ideal introduction and will be of value to all those working in ENT, oral and maxillofacial surgery, as well as anaesthetists, physicists and theatre operating staff.

Contents The Co_2 laser · Laser safety in the operating room · Anaesthetic considerations · CO_2 laser techniques and their effect on tissues · The CO_2 laser in the management of laryngeal disorders · The CO_2 laser in the oral cavity · The nose, the pharynx and the ear · Respiratory obstruction · Complications in CO_2 laser surgery · Future developments · Appendix: the KTP-532 Nd-YAG laser, an alternative to the CO_2 laser · Index

August 1988 224 pages 234 x 165mm Hardcover Illustrated – 14 line and 66 half tones 0 7236 05874 £45.00

A new solution for liver preservation

It is now 25 years since the first human orthotopic liver transplant was performed by Dr Thomas Starzl in Denver and 20 years since the first such procedure was performed by Sir Roy Calne in Cambridge. The intervening years have seen many advances in patient management and immunosuppression with steadily improving results. The 1983 NIH Consensus Conference concluded that 'liver transplantation is a therapeutic modality for endstage liver disease that deserves broader application'[1] and in recent years there has been a rapid increase in both the number of units undertaking liver transplantation and the number of patients receiving such grants.

One of the areas of deficiency identified in the consensus report was in preservation of the liver before transplantation. In the early days of liver grafting the donor organs were all retrieved following hypoxic cardiac arrest after discontinuing ventilation. To minimize the additional ischaemic insult of added storage time for transportation it was the practice to use only donors in the same hospital or occasionally, as in Sir Roy Calne's early cases, to transport the recipient and a full support team to the donor hospital[2].

The work of Collins *et al.*[3] on the kidney and Schalm *et al.*[4] on the liver added the concept that a solution might be used to supplement the effect of core cooling and hypothermia, allowing longer preservation periods. These solutions were rapidly taken into clinical practice, the Cambridge group using a modified version of Schalm's solution[5] and most others adopting Collins' solution. In this way distant procurement of livers became possible[5] and acceptance of the concept of brain stem death[6] and the 'heart beating donor' allowed the removal of organs in optimal condition. Preservation times could then be safely extended to 6–8 h and in some cases even to 12–14 h. In the human kidney, storage periods of 24–30 h are routine using simple cold storage techniques and the failure to achieve similar storage times in the case of the liver was attributed to the metabolic complexity of the hepatocyte rather than to any deficiency in the storage solution. Experimentally, longer preservation times were achieved using machine perfusion or combinations of drugs with modified storage solutions but these techniques proved too complex to gain widespread acceptance.

The major factor in organ preservation is hypothermia. This reduces the cell's metabolic requirements and prolongs the period it is able to survive under anoxic conditions. However, hypothermia also disrupts the cell's normal homoeostatic mechanisms and the loss of the cellular mechanism for volume regulation is thought to be particularly damaging. Most organ preservation solutions contain impermeant substances such as glucose, mannitol and citrate which remain in the extracellular space and thus osmotically inhibit hypothermic cell swelling. The hepatocyte, however, is freely permeable to many such agents, offering a possible explanation for the failure of these solutions in the liver. In 1986 Wahlberg *et al.* described a preservation solution for the pancreas based on the trisaccharide raffinose and the lactobionate anion[7]. In their initial tissue slice studies the raffinose and lactobionate combination was also shown to be effective in suppressing cell swelling in hepatocytes. It thus appeared potentially useful for liver preservation and this was confirmed in 1987 by a member of the Cambridge group working in the same laboratory in the University of Wisconsin in Madison[8]. Dog livers were successfully transplanted after 24–48 h cold storage using Wahlberg's original formulation but omitting dexamethasone, or using a simplified variant also omitting hydroxyethyl starch and adenosine. The original solution[7], now known as UW solution, has since entered widespread clinical use in trials in both the USA and Europe with livers being stored for more than 24 h on several occasions.

The implications of this new solution are considerable. In Cambridge we have used a simplified variant in over 60 liver transplants with preservation times of up to 17 h, allowing operations to be performed as 'semi-elective' procedures during daylight hours with full support services readily available. In the case of unanticipated difficulty in the recipient hepatectomy the dissection can be carried out slowly and carefully without fear of compromising the graft due to the lengthening preservation time. Transport and sharing of precious organs for transplantation is possible over even greater distances and the difficult logistical tasks involved in co-ordinating donor and recipient procedures have been simplified. Already a liver has been transported from North America on a scheduled commercial flight and transplanted in Paris. The

0007–1323/89/020107–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

solution is highly effective in preservation of the pancreas and the kidney. Its application in transplantation of these organs is undergoing clinical trials and early experimental results suggest that it will also prove effective in heart preservation.

The importance of this solution lies not only in its effect on liver transplantation but, more importantly, in its effect in restoring enthusiasm and interest in the field of organ preservation, a field which for many years has attracted little interest in the absence of any apparent clinically applicable progress. It is already clear that the new solution is over-complex, containing as it does many components included for purely theoretical reasons or incorporated from machine perfusion practice but not necessarily needed in cold storage[10]. I feel sure that the coming years will see many more new and effective solutions being produced to the benefit of transplant surgeons, who will be able to spend their nights in bed rather than in the operating theatre, and of their patients who will receive a better preserved organ under the best conditions possible to ensure success.

Cryptorchidism

In 1762 John Hunter concluded that the testicle was directed in its descent by the gubernaculum—the word meaning 'helm', or 'helmsman'—and, if descent were arrested, he said '... it is not easy to ascertain the cause of failure of descent, but I am inclined to suspect the fault originates in the testicles themselves'. Some 200 years and many written words later it is still 'difficult to ascertain'. The condition is known to be commoner in boys whose mothers have been exposed to exogenous oestrogens during pregnancy. The source of the oestrogen is, in some instances, a pregnancy test and, in others, perhaps the unwitting continuation of the contraceptive pill during early pregnancy. There is also an increased incidence in the offspring of obese mothers and in first born boys, and there is an unexplained seasonal variation. The apparent importance of hormonal factors in testicular descent has stimulated a great deal of research, some directed at producing 'medical' as opposed to 'surgical' treatment. The latest, an investigation into the use of luteinizing hormone releasing hormone, has proved disappointing. Although luteinizing hormone is easier to administer in a nasal spray, there appear to be few significant advantages over the previously used human chorionic gonadotrophin. No testis which is impalpable can be encouraged to descend, and there is still the suspicion that the testis which does would have done so anyway at, or before, puberty.

The descent of the testis from its original site on the posterior abdominal wall has been described in two phases: firstly, intra-abdominal descent and, secondly, after the 28th week of gestation, that in which the testis enters the inguinal canal to emerge from it to pass into the scrotum, between the 34th and 40th week. It follows that in babies born prematurely, and many more such babies are surviving, there will be a higher incidence of cryptorchidism. Although the mechanism of descent is not fully understood, the factors influencing the first phase include differential growth of the fetus in relation to the position of the developing testis and possibly changes in the pressure of the coelomic fluid. The gubernaculum plays an important part in the second, or true phase of descent, although by what means is not yet clear. Indeed, there is not even universal agreement about its morphological structure.

Terminology

Although testicular position can most easily be defined as normal or abnormal, one of the problems besetting the subject has been terminology. Terms such as 'imperfectly descended', 'undescended', and 'maldescended', have been commonly used, sometimes to describe the same condition. The term cryptorchidism has come into wider use in recent years and although literally meaning 'hidden testis' (Greek: *cryptos*: *orchis*), it is reasonable to accept it as describing any abnormally positioned testis.

The normal testis includes the scrotal testis and the retractile testis. After the neonatal period the scrotal testis may be drawn up by the cremasteric muscle to a high scrotal or an inguinal position. In the inguinal position it is held in the superficial inguinal pouch which is slightly lateral and superior to the external inguinal ring. The cremasteric reflex is not present in the newborn and so it is important that as part of the immediate postnatal examination by paediatrician or midwife, the testicular position is recorded. For practical purposes, the testis which has been accurately recorded as in the scrotum at birth and which in later years is found to be higher in position, is a normal retractile testis. Differentiation between a testis which is inguinal or high scrotal and retractile, and a testis which is in the same position but held there abnormally and has never been low in the scrotum, may be most difficult without the neonatal record. In one instance the testis is normal, in the other abnormal.

The abnormal testis is never low in the scrotum and cannot be manipulated into this position. It may be held up on the normal track (the imperfectly descended testis) where it is palpable if it lies outside the external ring, and impalpable if it lies within the inguinal canal (the canalicular testis) or the abdominal cavity. The abnormal testis may also, rarely, be palpable in one of the subcutaneous ectopic positions (the maldescended testis), for example, perineal or femoral. The clue to diagnosing an ectopic testis may be the presence of a palpable spermatic cord at the external inguinal ring, so leading the examiner to the misplaced testis. Palpation for the cord at this site, which may be quite difficult in a podgy infant, is an essential part of clinical examination for, if

0007–1323/89/020109–04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

present, it will also raise the question whether the testis has atrophied (the vanishing testis). Such atrophy, which is a commoner finding than ectopia, occurs following pre-, peri- or unrecognized postnatal torsion, or after vascular injury during herniotomy or orchidopexy.

Two further points regarding the nomenclature and clinical examination must be made. The abnormal testis may be held up in the superficial inguinal pouch, owing to abnormal gubernacular attachments in this region, or to a fascial barrier preventing its access to the scrotum, or both. It has been classified as an 'inguinal ectopic testis', although it lies in a pouch in which the normal testis may be found. It would be better, perhaps, if this abnormality were referred to, as some have in the past, as the 'obstructed' testis. It is not an uncommon cause of cryptorchidism and its differentiation from a retractile testis in an anxious boy with a well developed cremasteric reflex may tax even the most experienced. The second, and less common problem, has been recognized only in recent years. It had always been assumed that a boy diagnosed as having a rectractile testis would, at puberty (when the cremasteric reflex no longer resulted in retractility), have a normal scrotal testis. As a result routine outpatient follow-up of boys with 'retractile testicles', was not thought necessary. It is now clear that there is a small group in whom the retractile testis does not descend as expected; in fact, with growth the testis appears to become more difficult to manipulate into the scrotum, if not actually to ascend (the ascending testis). The probable explanation is that there is a coexisting hernial sac or processus vaginalis which prevents cord lengthening as the boy grows. The implications are that any boy in whom there is the least difficulty in manipulating the testis below the mid-scrotal level should be followed up at least annually.

Incidence

In a study in the late 1950s of more than 3000 babies delivered in a hospital in west London, and followed up for 1 year, Scorer[1] found the incidence of cryptorchidism to be about 0·8 per cent. More recently, a study of orchidopexy rates derived from the Hospital Inpatient Enquiry, suggests that the incidence of cryptorchidism may have doubled in the past 20 years[2]. This latter inquiry was initiated because cryptorchidism is the major risk factor for later testicular malignancy; some 10 per cent of patients with testicular cancer give a history of cryptorchidism.

To confirm the impression of an increase in cryptorchidism an investigation was conducted of all boys born in the John Radcliffe Hospital, Oxford, between November 1984 and October 1986[3]. The overall incidence of cryptorchidism at birth was 5·9 per cent and by 3 months this had dropped to 1·6 per cent. For babies of birthweight $\geqslant 2{\cdot}5$ kg the rate was 4·8 per cent which dropped to 1·4 per cent by 3 months. There was a higher incidence of cryptorchidism in smaller babies and a higher rate of descent by 3 months, i.e. there was a clear decrease in cryptorchidism rate with increasing birthweight. Therefore the suspected increase in cryptorchidism was confirmed. This increase, however, does not match the increase in orchidopexy rates. While there may be some distortion in the orchidopexy figures due, for example, to the inclusion of boys having testicular fixation following torsion, or having orchidopexy associated with herniotomy, the suspicion is strong that orchidopexy is being performed too frequently[4].

The timing of orchidopexy

Review of the literature regarding fertility is complicated by the variability of the reported studies. For example, there is a possibility that those being examined may have had normal retractile rather than abnormal testes, or that the groups examined represent a selected sample, or that methods of semen collection and analysis were different. After analysis of the literature relating to children who underwent orchidopexy between the ages of 4 and 14, Chilvers *et al.*[5] suggested that there was little evidence that operating early or, indeed, operating at all had an effect on subsequent fertility. Of unilateral treated cases 15 per cent were azoospermic and 30 per cent oligospermic, while in bilateral treated cases 42 per cent were azoospermic and 31 per cent oligospermic. It is to be hoped that very early operation will improve these figures, a hope which is encouraged by histological studies of cryptorchid testes which demonstrate that significant morphological changes do not appear until the end of the second year of life.

There is no proof that orchidopexy protects from later malignant change, although it is clearly advantageous for the testis to be in a scrotal position where an abnormality may be recognized early. An intra-abdominal testis appears to be at greater risk of malignant change than an abnormal inguinal testis. It is probable that the factor (or factors) which causes abnormal testicular position is also responsible for the predisposition to malignancy, although the subject is further complicated by the fact that in some adults with testicular cancer the cryptorchidism has occurred in the contralateral testis.

As the tendency for further descent of the testis may continue during the first year of life, especially in low birthweight infants, it is important to avoid too early operation if there is any uncertainty regarding the abnormality of testicular position. If there is no doubt, operation within the first 6 months seems most appropriate on present evidence. Ideally, surgery should not be delayed beyond the age of 2 years. It must be recognized, however, that the operation is technically more difficult in the very young and trauma to the testicular vasculature or vas is a real risk. Some estimates in the past, when operation was usually performed in older children, have put the postorchidopexy atrophy rate as high as 10 per cent. This is not a procedure to be undertaken by the unsupervised surgical trainee.

It has been accepted that in terms of psychological disturbance the most unsuitable ages for hospitalization and operation are between 18 months and 4 years. It may well be that day case admission with a parent continually present in the ward, and accompanying the child to the anaesthetic room has made this less important. However, with accurate, early diagnosis the surgical treatment of cryptorchidism should in future, for reasons of preserving testicular maturation, be complete by 1 year or 18 months of age. Some boys will undoubtedly escape this diagnostic net in these early years but, it is hoped, will be diagnosed at a pre-school medical examination at 4 years old. Early treatment seems likely to forestall the psychological problems which have been attributed to testicular abnormality; there is now no place for 'waiting to see what happens at puberty'. The insecure or embarrassed adolescent with an absent testis may be offered the cosmetic advantage of a prosthesis.

An abnormal, but palpable testis can almost always be sufficiently mobilized at operation to be placed in the scrotum. Fixation is best performed by placing the testis in a pouch between the dartos muscle and the skin, although some still prefer to place the testis in the opposite scrotal compartment. Fixation to the fascia of the thigh or by the use of rubber bands are of historical interest only.

Adequate mobilization of the testis sited just within the internal inguinal ring or in the inguinal canal itself, sometimes may be difficult, even using additional retroperitoneal dissection[6]. In these circumstances orchidopexy may be staged, initially fixing the cord and testis in the inguinal canal within fine Silastic® sheeting (Dow Corning, Reading, UK). This prevents adhesions, which otherwise make the second stage operation a year or so later both difficult and risky to the testicular vessels. Although this procedure has been criticized on the grounds that the need for it represents inadequate mobilization, it is far preferable to over-zealous mobilization which produces vascular damage.

The true intra-abdominal testis which, at operation, may be diagnosed by preliminary laparoscopy, can rarely be mobilized sufficiently by standard techniques and if there is a normal contralateral testis the most appropriate treatment may be orchidectomy. However, the vasal vessels from the inferior epigastric vessels may be able to maintain the testicular blood supply through collaterals. If this appears to be the case, trial clamping of the short testicular vessels, followed a few minutes later by a small incision into the tunica albuginea to ensure there is fresh bleeding, may allow the testicular vessels to be divided, so providing considerable additional length. It is a matter of judgement whether this manoeuvre should be the first stage of a two stage procedure, or should be followed immediately by placing the testis in the scrotum, for this significant alteration in the position of the collateral vessels may compromise their effectiveness and perhaps account for some of the poor reported results. Microvascular anastomosis of the divided testicular vessels to the inferior epigastric vessels has been practised recently, with a number of small series showing success rates of 60–100 per cent. This method demands considerable microvascular experience and the results of such operations on the very young—before irreversible changes have occurred in the testis—remain to be assessed.

The whole subject of the abnormal testis in childhood has been admirably reviewed by Hazebroek in his book *The Treatment of Cryptorchidism*, published in 1986[7]. Its findings support Russell's views on the importance of operative technique[8] and point to the need for the management of this condition to be a responsibility of paediatric surgeons or general or urological surgeons with specialist experience in children's surgery.

Current management of venous thromboembolic disease

Despite improvements in early diagnosis, medical management, and prophylaxis of venous thrombosis, pulmonary embolism continues to be a vexing and frequently fatal problem. Estimates of the incidence of fatal pulmonary embolism in the USA continue to range from 50 000 to 100 000 or more annually[1,2]. In spite of this high incidence, the management of patients with established thromboembolic disease remains controversial.

The initial question faced by the clinician managing a patient with a new diagnosis of deep venous thrombosis is whether to treat with conventional anticoagulation or to attempt to remove the thrombus with one of the newer thrombolytic agents or use a surgical approach. While surgical thrombectomy was commonly performed in the past, it has been abandoned for most deep venous thromboses because of the high rate of rethrombosis. Recently there has been a resurgence in interest in surgical thrombectomy for severe iliofemoral venous thrombosis causing phlegmasia cerulea dolens or phlegmasia alba dolens. The incidence of rethrombosis has been reduced in these patients by the creation of a temporary distal arteriovenous fistula. Nevertheless, the use of surgical thrombectomy should be reserved for this very select group[3]. There have been several studies comparing anticoagulant therapy and thrombolytic drugs for the treatment of acute deep venous thrombosis. Serial venographic studies have shown that heparin is quite effective in preventing extension of the thrombotic process but that only a small amount of thrombolysis occurs during treatment with heparin. In contrast, approximately 50 per cent of patients treated with thrombolytic therapy will have significant lysis of thrombus. It appears that the age of the thrombus is the most important factor in determining the likelihood of lysis[4]. There is a significant cost to this increased lysis, however, and that is the 2·9 times greater incidence of bleeding complications in patients treated with lytic therapy compared with those treated with heparin.

The advocates of lytic therapy for deep venous thrombosis propose that such therapy will result in better preservation of venous valvular function and thus reduce the incidence of late post-phlebitic syndrome and chronic venous insufficiency. As yet, however, there has been no large scale comparative study to support this contention.

Based on current available data, it is recommended that surgical therapy be reserved for patients at immediate risk for venous gangrene due to the phlegmasia syndromes. Fibrinolytic therapy may be considered for patients with extensive venous thrombosis but who do not require immediate surgical decompression and for those in whom lysis of thrombus can occur over 24–48 h. Patients with lesser degrees of venous thrombosis are best treated with conventional heparin anticoagulation and heparin should also be administered to patients following a course of fibrinolytic therapy.

After an episode of venous thrombosis, patients remain at risk of recurrent thrombosis for an undetermined period. Conventionally, patients have been anticoagulated with warfarin following 7–10 days of heparin therapy. The warfarin has been continued for from 3 to 6 months. There is a significant risk of bleeding complications with warfarin and, because of this, recent trends have been to lower the dose to prolong the prothrombin time by a ratio of 1·2 : 1·5 rather than the previous goal of prolongation by a factor of two. The lower dose appears to be equally effective in preventing recurrence of venous thromboembolism and is clearly associated with a lower incidence of bleeding complications[5].

The management of established pulmonary embolism is perhaps even more controversial than the management of simple deep venous thrombosis. Heparin has been compared with no treatment for established pulmonary embolism, but this trial had to be discontinued because of the clear superiority of anticoagulation compared with no treatment[6]. The mortality rate for undiagnosed and therefore untreated pulmonary embolism is over 30 per cent, while the mortality rate for acute pulmonary embolism in patients treated with heparin is less than half this figure. Heparin therapy allows the body's actual fibrinolytic system to lyse sufficient volumes of thrombus to restore right ventricular and pulmonary pressures to normal, but this process requires several weeks[7].

The primary decision facing the clinician caring for a patient with pulmonary embolism is to decide between heparin and one of three thrombolytic agents. Of the five trials comparing fibrinolytic agents with standard heparin therapy, all have shown improved clot lysis in patients treated with fibrinolytic agents compared with patients treated with heparin. However, this has not been translated into improved mortality or

0007–1323/89/020113–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

improved pulmonary function either early or late[8]. In addition, this fibrinolytic therapy has been used at the cost of an increased incidence of bleeding which may be severe or even fatal. It was hoped that with the introduction of recombinant tissue-type plasminogen activator a more thrombus specific lytic agent would be available and that the incidence of bleeding complications would be reduced. However, recent clinical trials using recombinant tissue-type plasminogen activator have also shown a significant incidence of bleeding complications[9]. Additionally, it must be realized that all of the fibrinolytic agents require 7–12 h for maximal lysis and improvement in pulmonary haemodynamics.

It is expected that the use of fibrinolytic agents for pulmonary embolism will increase. Because of the increased incidence of bleeding, however, the use of these agents should be reserved for patients with haemodynamic compromise but who do not require immediate surgical pulmonary embolectomy for survival.

Ligation and permanent interruption of the vena cava in an effort to prevent subsequent embolization of lower extremity or lower vena caval thrombi have been previously recommended. However, the high incidence of severe venous stasis and post-phlebitic syndrome subsequent to complete interruption of the vena cava suggests that this should be done only in extreme circumstances. In 1972, Greenfield introduced an intravascular cone-shaped filter for the purpose of trapping larger emboli. This device has become the most popular intravascular device for prevention of pulmonary emboli and thousands have been inserted. However, these devices are not innocuous. Filters have been found later in the heart[10], in the renal and suprarenal position, as well as in the iliac veins[11]. Perforation and injury to retroperitoneal organs may occur[12]. Current design allows percutaneous insertion through the femoral vein. However, the large size of the catheter and thus the degree of injury to the femoral vein is such that exacerbation of the lower extremity venous thrombosis syndrome by femoral vein thrombosis at the site of cannulation may occur in as many as 40 per cent of insertions[13]. A smaller apparatus for introduction currently being developed may improve this alarming rate, but this new device is not yet available for general use.

The indications for insertion of a filter include pulmonary embolism in the presence of an absolute contraindication to anticoagulation such as recent intracranial haemorrhage or an extensive surgical procedure. It may also be used in patients who experience major bleeding episodes while on anticoagulation for embolism. Recurrent embolism while on adequate anticoagulation therapy is exceedingly rare but is an indication when it occurs. A large number of filters are being inserted for prophylactic reasons[14], but in view of the problems mentioned above, this practice may be viewed with circumspection and requires continued reassessment.

This review examines current knowledge regarding the metabolic responses to trauma and sepsis. The factors which may mediate the responses are discussed and the potential value of pharmacological or nutritional manipulation is reviewed.

Keywords: Metabolic response, sepsis, trauma

The accelerated breakdown of skeletal muscle following significant injury was first identified by Cuthbertson more than 50 years ago[1]. He divided the response into a short-lived 'ebb' phase, corresponding to the period of hypovolaemia and sympathetic activity immediately after injury, and a more prolonged 'flow' phase which is characterized by a negative nitrogen balance. A catabolic state similar to the flow phase of trauma also occurs in patients with established sepsis, and many parallels can be drawn between the metabolic profile of the severely injured and septic patient. This article is a review of the present knowledge of the metabolic responses to trauma and sepsis. Contention persists over some aspects of the nature of these responses and the factors which mediate them, and data and interpretations of the polemical issues will be presented.

The consequences of a prolonged catabolic response are now seen more frequently as intensive care facilities prolong the survival of multiply injured and severely septic patients. Although modern techniques of enteral and parenteral nutrition are able to reduce the rate of consumption of protein and energy reserves it is not yet possible to achieve a positive nitrogen balance in severely stressed patients[2]. The last section of this review discusses the impact of intravenous nutrition on the metabolism of septic and trauma patients and summarizes the results of experimental work with agents which promote protein conservation in this setting.

Mediators of the metabolic response to sepsis and trauma

It is well established that the neuroendocrine response to sepsis and trauma effects many of the observed changes in metabolism (*Figure 1*). More recent work has suggested that inflammatory mediators released from the wound itself or from a septic focus may also play a part in these changes[3]. Despite extensive investigation there remains much conjecture about the nature of the link between tissue insult and the resultant metabolic response.

The neuroendocrine response

Injury is followed by an outpouring of sympathetic activity and a clearly positive relationship has been established between the injury severity score[4] (ISS) and the plasma concentration of adrenaline, noradrenaline and dopamine[5,6]. The plasma catecholamine levels are maximal shortly after injury, but this response is short lived and the plasma levels have usually returned to the normal range within 24 h[7]. Although it is possible to relate plasma hormonal levels to the ISS score we have recently demonstrated that there is no correlation between the ISS score and the degree of metabolic abnormality seen in patients after blunt trauma[8]. The metabolic response in these patients appears to be an 'all or none' response—the patient with an ISS of 15 is metabolically similar to the patient with a score of 50.

At the same time as the sympathetic nervous system response, the hypothalamic–pituitary axis is also activated. However, the relationship between injury severity and plasma cortisol is not direct: cortisol levels peak at an ISS of 12 and then become lower with more severe injury[9]. In addition, the cortisol response is transient and the plasma cortisol level falls to normal within a few days of injury Furthermore, the correlation between hormonal changes and metabolic abnormalities is difficult to show; for example we have found no correlation between the plasma cortisol level and the degree of alteration in either glucose or protein kinetics[8].

The plasma concentration of growth hormone is raised for 24 h after injury[10], as is that of prolactin. Following thermal injury antidiuretic hormone levels have been reported to be ten times control values[11]. Aldosterone is increased[12], the renin–angiotensin system is activated[13] and glucagon levels rise markedly about 12 h after major injury[14].

Thus, the ebb phase of injury is associated with increased sympathetic activity and an outpouring of counter-regulatory hormones. However, during the stage of maximal nitrogen loss in the flow phase (about 7–10 days after injury) the catecholamine, glucagon and cortisol plasma levels are not raised[13]. This is, however, the time when the plasma insulin level rises to a peak[15].

Although the catabolic response during the postinjury flow phase and established sepsis is similar, there exist differences in the hormonal milieu between these two conditions; the counter-regulatory hormones remain high in septic patients and the elevation of insulin levels is not a consistent feature[13].

There has been a recent attempt to simulate the hormonal responses associated with injury in normal volunteers to elucidate the role of hormones as mediators of the metabolic change seen following trauma[16]. Nine volunteers received a continuous 74-h infusion of the three 'stress' hormones

0007–1323/89/020115–08$3 00 © 1989 Butterworth & Co (Publishers) Ltd

(cortisol, glucagon and adrenaline) at a rate which produced plasma levels similar to those seen following mild to moderate injury. The infusion resulted in a significantly raised basal metabolic rate, hyperglycaemia, hyperinsulinaemia and insulin resistance, and a negative nitrogen balance. Further studies with single hormone infusion indicate that there is a synergistic action between the three hormones. The researchers concluded that the simultaneous release of stress hormones may be responsible for mediating the metabolic response to injury.

Inflammatory mediators

It is not possible to explain the complete spectrum of metabolic changes seen in septic and injured patients by the neuroendocrine response as it is presently understood. This has provoked the search for other mediators. Recent research has suggested that interleukin 1, a protein released by macrophages at sites of inflammation, plays a part in the afferent link between damaged tissue and the central nervous system. This new work is discussed further in relation to protein metabolism (see below). Wilmore has recently described synergism in the action of inflammatory and endocrine mediators and concluded that both are integral factors of the metabolic response to sepsis and trauma[3].

Energy production

Cuthbertson's appealingly simple description of a hypometabolic ebb phase and hypermetabolic flow phase[17] has undergone substantial modification in the light of more contemporary research. There is little evidence from clinical studies to suggest that heat production is reduced during the ebb phase[18], and it is likely that the increase in metabolic rate during the flow phase is not as large as previously thought[13]. None the less a modest increase in resting energy expenditure in the flow phase is commonly observed and, in the extreme case of extensive burn injury, this increase may be as great as 100 per cent[19]. The maximal increase in resting energy expenditure coincides with the maximal rate of protein catabolism and occurs around 1 week after injury

Numerous factors have been proposed to account for the extra heat production, such as the increased oxygen consumption of the injured tissues, increased energy expenditure by the heart, the Q_{10} effect of raised body temperature, the thermic effect of accelerated protein breakdown and the heat of evaporation lost from burn surfaces[13,20]. The matter has been the subject of a concise review by Little who concludes that the underlying mechanism is probably a resetting of hypothalamic regulatory control[21] Yet a further explanation has recently been advanced: it is known that in trauma patients there is an increased rate of substrate recycling in which triglyceride is hydrolysed and then re-esterified, and glucose and its glycolytic intermediates are recycled. As there is no net production of free fatty acid or glucose during these cycles but ATP is hydrolysed, such recycling represents an energy drain Wolfe *et al.* have recently quantified the energy dissipated by such substrate recycling and, although their methodology grossly underestimates the extent of these processes, they conclude that it is possible that these cycles provide the principal biochemical explanation for the increased heat production seen in trauma patients[22].

Glucose metabolism

The post-traumatic ebb phase and the earliest stage of sepsis are both characterized by hyperglycaemia[23]. This rapidly established response is initially the result of enhanced glycogenolysis[24] and later a consequence of increased glucose production coupled with reduced peripheral utilization[23]. Sympathetic activity and circulating adrenaline provide the stimulus for hepatic glycogenolysis and encourage glucagon release while simultaneously inhibiting insulin release from the endocrine pancreas[25–27] The release of cortisol probably plays a facilitatory part in this response[28] The plasma glucose levels subsequently fall during the post-traumic flow phase to less elevated or normal levels[29,30].

However, the plasma glucose level gives little indication of glucose turnover and this has been the subject of much recent investigation. It is generally agreed that in septic and flow phase trauma patients, glucose turnover is increased and that gluconeogenesis is enhanced despite freely available plasma glucose, but there is controversy over changes in glucose oxidation in these situations[31].

Gluconeogenesis

In health, gluconeogenesis is effectively inhibited by an increase in blood glucose levels. However, hepatic glucose production is maintained at normal or elevated rates during the high flow response to trauma or sepsis[32–34] despite the hyperglycaemia characteristic of such severely ill patients The suppression of gluconeogenesis by glucose infusion is very much less effective in septic and trauma patients than in normal volunteers[35–37]. This reduction in the suppressibility of gluconeogenesis is probably caused by the increased availability of gluconeogenic substrates occurring in a favourable hormonal milieu[23,26,28]. In severely stressed patients, muscle glycogenolysis and the metabolism of hypoxic tissues produce lactate, glycerol is released from adipose tissue, and plasma alanine levels are increased as a result of enhanced proteolysis[34,38]. In burn patients it has been determined that lactate is quantitatively the most important gluconeogenic substrate[23]. Previously we have demonstrated an increase of 40 per cent in the rate of appearance of alanine and a 100 per cent increase in the rate of appearance of glycerol and availability of lactate in trauma patients[8]. On the basis of 2 mol of either alanine, glycerol or lactate being required to produce 1 mol of glucose it is likely that this substantial increase in three carbon substrates would be adequate to explain the observed increase in basal glucose appearance seen in these patients.

However, in recent work by Jahoor *et al.*[39] in burn patients in which both insulin and glucagon concentrations were lowered simultaneously by infused somatostatin, hepatic glucose production decreased despite an increase in the delivery of alanine to the liver. These results suggest that glucose production is controlled at the liver and not by precursor supply.

Glucose oxidation

Although most investigators report that glucose oxidation is increased during the high flow phase and sepsis in absolute terms, there remains disagreement over whether glucose is oxidized as efficiently as in healthy volunteers[40]. The Manchester Trauma Unit researchers have found an increase in glucose oxidation in relation to plasma glucose in injured patients, which they interpreted as a consistent response of substrate mobilization and oxidation[30]. However, the situation is far from clear: there exists a considerable body of data derived from isotopically labelled substrate studies which suggests that glucose is oxidized less efficiently in septic and trauma patients[8,29,31,41–43]. The recently reported reduced activity of the pyruvate dehydrogenase complex in septic rats suggests that intracellular derangements in enzymatically controlled pathways may account for the observed reduced efficiency of glucose metabolism[44].

It is germane to the interpretation of the data reported on glucose kinetics that the rate of glucose clearance from the plasma is not related to the rate of glucose oxidation or even to the percentage of glucose uptake oxidized[45]. Therefore, it is unlikely that reduced glucose oxidation is simply a consequence of the prevailing insulin resistance.

Insulin

Although changes in insulin release and responsiveness in septic and trauma patients have been well documented[46–48], the role of this hormone in the metabolic changes associated with these conditions remains to be clearly defined.

The sympathetic discharge following severe burns has been associated with an inhibition of insulin release[25], although a low plasma insulin level is not a consistent feature of the immediate postinjury period[15]. Plasma insulin levels subsequently rise to reach a peak several days after injury of up to three times basal levels[49]. This coincides with the period of maximal catabolism[50].

During the flow phase, the plasma insulin level is inappropriately high for the plasma glucose concentration[30] with the pancreas showing a normal or augmented response to glucose infusion[51,52]. However, this phase of the metabolic response is characterized by insulin resistance.

The high levels of insulin fail to suppress glucose production, and there is a reduction in glycogen storage[29], lipolysis and fat oxidation[53] Frayn has demonstrated a highly significant correlation ($r=0{\cdot}97$) between the plasma insulin concentration and nitrogen loss in trauma patients and concludes from this finding that protein turnover is resistant to the normal anabolic effect of insulin[15]. However, Jahoor *et al.* have found in burn patients that insulin acts to conserve protein by restraining the release of amino acids from peripheral tissues[39]. Wilmore has similarly demonstrated a protein anabolic effect of insulin despite profound insulin resistance to carbohydrate in the skeletal muscle of injured patients[54]. The nature of the changes in insulin receptors has not been accurately characterized, although it is likely that there are changes at both the receptor and post-receptor level[55]. Experimental animal models most clearly implicate glucocorticoids as a cause of insulin resistance[56], although the mechanism of this response is yet to be fully elucidated.

The adaptive value of fuel store mobilization

The mobilization of fuel reserves in trauma and sepsis is common to several species of laboratory animal studied and is likely to be of adaptive value. Infusion of hypertonic glucose has been shown to decrease mortality in pigs following severe haemorrhage[57] and this manoeuvre has also resulted in a rapid increase in blood pressure in recently injured battle casualties[58]. It has been suggested that the observed pressor effect is due to a mass action effect of glucose increasing myocardial glucose uptake and hence the availability of glucose for anaerobic glycolysis[58]. Hyperglycaemia will also compensate for intravascular fluid losses.

The increase in gluconeogenesis and its reduced supressibility during exogenous glucose administration in the post-trauma flow stage and in sepsis may reflect the influence of the damaged and reparative tissues on the rest of the body[59]. The cells involved in inflammation and wound repair rely on glucose as a primary fuel which they predominately metabolize anaerobically. The wound may be looked upon as a privileged organ whose glucose demands can account for most of the approximate doubling in glucose turnover seen in severely burned patients. Wilmore concludes that the increased glucose turnover provides essential fuel for inflammatory and reparative tissue which optimizes host defences and ensures wound repair[54].

Fat metabolism

The complex changes in the mobilization and oxidation of fat in sepsis and trauma have not been as fully unravelled as those in carbohydrate metabolism. Again it is appropriate to discuss the post-trauma changes in the ebb and flow phase, and again there are parallels to be drawn between the flow phase and established sepsis.

Lipolysis is enhanced immediately after injury by the stimulation of the sympathetic innervation of adipose tissues and by raised plasma adrenaline, glucagon and cortisol levels[38]. Growth hormone may also play a part in this response[60]. The accelerated lipolysis occurs despite the prevailing hyperglycaemia and raised plasma insulin[61]. There is, however, little correlation between plasma free fatty acid levels and the severity of the trauma[24,62] This is probably a result of the reduced perfusion of adipose tissues which often follows severe trauma, so that the supply of albumin carriers for released free fatty acids is inadequate[63]. In addition, the plasma free fatty acid level is lowered further by the lactic acidosis of systemic hypoxia which encourages re-esterification[64].

Septic patients have a lower respiratory quotient (RQ) than non-septic controls, and worsening sepsis is frequently accompanied by progressive falls in RQ. These findings have been corroborated by isotopic studies and suggest that increased fat oxidation may be an important feature of the altered metabolism seen in sepsis[65–67]. During the first few days after severe injury the RQ rises from a value of close to 0·7 to one that indicates that carbohydrate is the major fuel[13]. Glucose infusion in normal volunteers inhibits fat oxidation and the RQ rises above 1·0 as the excess glucose is deposited as triglyceride. However, in patients with severe sepsis, although the RQ rises following glucose infusion it does not reach a value of 1·0 indicating that fat continues to be the main substrate for oxidation[51].

Under most circumstances the rate of uptake of free fatty acids is directly proportional to their plasma concentration[68]. However, the increase in fatty acid oxidation in sepsis and trauma is not 'substrate led' as the plasma levels of free fatty acid are often quite low[30]. This suggests that there are changes in the intracellular metabolism of fat in these patients[38].

The preference for fat as an energy substrate is more pronounced in septic than in trauma patients[66]. Using the sepsis severity scale developed by Elebute and Stoner[69], it has been shown that there exists a positive relationship between fat oxidation and sepsis severity, whereas there is a negative relationship with glucose oxidation[66].

Less is known about changes in triglyceride metabolism. It has been reported that the concentration of triglyceride in plasma is elevated in Gram-negative sepsis[70] and after injury[15]. There is presently no isotopically-labelled triglyceride suitable for infusion into patients, but studies in septic animals have revealed that the increase in triglyceride concentration is owing to an accelerated rate of production of triglyceride, and in particular very low density lipoprotein, rather than the response being secondary to a decrease in triglyceride clearance[71,72]. The increase in activity of adipose tissue lipoprotein lipase is consistent with the postulated increase in very low density lipoprotein turnover[73].

Ketone metabolism

Simple starvation is attended by ketosis As ketone bodies can serve as alternative energy substrates for many tissues, they reduce whole body glucose demand and therefore gluconeogenesis from protein. However, in severe sepsis and, to a lesser extent, trauma there is a blunting of the adaptive ketonaemic response and its subsequent nitrogen conservation[74,75]. It is likely that the increased insulin levels seen in stressed surgical patients are responsible for the impaired production of ketone bodies[76], although reduced activity of hepatic acylcarnitine transferase has also been implicated[77].

Protein metabolism

The negative nitrogen balance described by Cuthbertson[1] has been similarly demonstrated in septic patients[78]. When this response is prolonged, the resultant protein depletion plays a major part in the pathogenesis of multiple organ failure which develops in severely injured or septic patients[79] A detailed understanding of the nature and mechanism of the protein loss is important to provide a basis for giving more effective nutritional support and offers the alluring possibility of metabolic manipulation in such cases.

Whole body kinetics in sepsis and trauma

A net protein loss may result from a relative decrease in whole body protein synthesis, an increase in catabolism, or a combination of both mechanisms. The varied responses reported following elective surgical procedures, musculoskeletal trauma, burns and sepsis are summarized in *Table 1*. The trauma

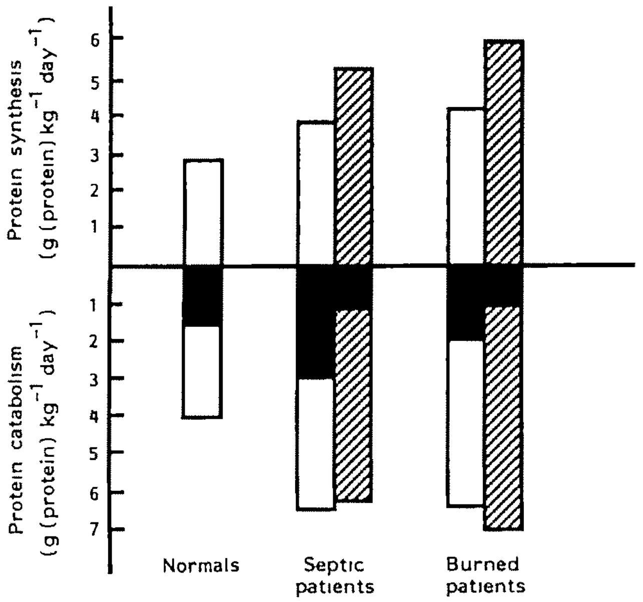

Figure 2 *Rates of total protein synthesis, total protein catabolism and net protein catabolism in normal volunteers, septic patients and in burned patients. In septic and burned patients the rate of net protein catabolism is significantly greater* ($P<0.05$) *than in volunteers. Providing intravenous nutrition reduces net protein catabolism by significantly increasing total protein synthesis. The rate of total protein catabolism remains unchanged (modified from Shaw and Wolfe, 1987*[31]*.* □*, Basal nutrition (post-prandial at 12 h in normal volunteers),* ▨*, intravenous nutrition,* ■*, net protein catabolism*

of elective surgery results in an inhibition of protein synthesis, whereas catabolism proceeds at an unchanged rate[80-82]. However, in severe trauma involving multiple fractures or burns, or in septic patients, both synthesis and catabolism are increased, with the rate of protein degradation outstripping that of production[8,42,83,84] (*Figure 2*). The cause of this disparity in response is not clear, but it is likely that the postoperative changes primarily reflect the effect of starvation rather than the response to trauma *per se*. It is noteworthy that the acute metabolic response to severe injury and sepsis is the direct reverse of that seen in starvation in which both protein synthesis and degradation are reduced[85,86].

The preceding description of the relative changes in the relationship between net protein synthesis and catabolism oversimplifies the situation as it exists in the clinical setting as it does not include the influence of protein intake. This deficiency is rectified in the model developed by Clague and his colleagues[87], in which they propose that the protein breakdown in response to trauma is largely obligatory, whereas synthesis increases with substrate availability. Accordingly, provision of adequate protein can reduce net nitrogen loss after trauma.

Changes in skeletal muscle

Skeletal muscle is the major site of nitrogen storage and of nitrogen loss, although the contribution of other tissues such as skin, gut and lungs may not be insubstantial[88]. The rate of release of 3-methylhistidine, an amino acid derived exclusively from actin and myosin and excreted unchanged, has been used as an index of the rate of skeletal muscle breakdown[89]. Considerable increases in the rate of production of 3-methylhistidine have been seen in severely traumatized and septic patients[90], whereas no increase occurs following orthopaedic operations and minor injuries[91]. Although recent doubts have been voiced about the specificity of 3-methylhistidine as an indicator of skeletal muscle breakdown[92], other investigators have provided sound arguments for its continued use[93].

In injury, the increased rate of protein release from skeletal muscle does not simply represent the degradation of damaged tissue; there is increased loss of 3-methylhistidine and changes in skeletal metabolism in muscle undamaged by trauma[94,95].

The technique of percutaneous needle biopsy of human muscle[96] has enabled investigation of the intracellular metabolic derangements. The changes in intracellular amino acid concentration following elective surgery, trauma and in sepsis are similar, suggesting a common response to varying types of insult[97-99]. The response consists of an increase in essential amino acids, particularly branched chain amino acids, and reduction in non-essential amino acids largely as a result of a 50 per cent decrease in the level of intracellular glutamine[97] The cause of these changes remains a matter for conjecture[95-100].

Hepatic protein metabolism

The data of studies of whole body protein metabolism represent the summation of response of the body tissues, but fail to reflect variation in kinetics between different tissues In both severe trauma and sepsis, whereas skeletal muscle catabolism exceeds synthesis there is a net increase in the production of hepatic structural and secretory proteins[101,102].

The teleological explanation of the autocannibalism of muscle tissue in response to stress is that this mechanism allows greater than normal quantities of amino acids to be available to the liver for gluconeogenesis, oxidation and the synthesis of proteins involved in immune defence and wound healing[26,34,103]. This increased hepatic synthesis occurs at a time of depressed efficiency of other hepatic cellular functions[104,105], reflecting the high priority of this function in sepsis and trauma[106].

Mechanism of protein loss

The catabolism of muscle protein reserves to provide substrate for increased hepatic synthesis to defend against infection and promote wound healing is an appealing explanation of the changes in protein metabolism seen in sepsis and trauma. This presents the challenge of delineating the neuroendocrine changes which mediate this response.

It is known that physical rest, fever, starvation, glucocorticoids and insulin resistance[79,85,102] are associated with an increased net rate of protein breakdown, but that none of these stimuli induces protein catabolism to the degree seen in sepsis and trauma[107]. Glucocorticoids cause an increased amino acid release, increased oxidation of leucine by skeletal muscle and favour hepatic conversion of amino acid to glucose. However, it is generally believed that glucocorticoids have primarily a permissive role and are not responsible for the overall protein catabolism seen in sepsis and trauma[26]. We have demonstrated that glucagon plays a part in accelerating protein breakdown in trauma patients[108].

Recent work has suggested that factors produced by leucocytes may be central in promoting the changes in protein metabolism in sepsis and trauma. Interleukin 1, a polypeptide synthesized by macrophages as part of the inflammatory response, causes fever and leucocytosis[109]. Rat muscle incubated with interleukin 1 showed a stimulated rate of proteolysis but the protein synthesis rate was unaffected[110]. These effects may be mediated by prostaglandin E_2 as the interleukin 1 increased prostaglandin E_2 production and the catabolic effects of interleukin 1 can be abolished by the addition of indomethacin. When injected into the peritoneal space of rats, interleukin 1 increased the rate of synthesis of hepatic secretory and structural proteins[111,112]. The field of inflammatory mediators is advancing rapidly as new proteins are isolated and their actions described.

Consequences of a prolonged catabolic state

The breakdown of skeletal muscle that occurs in septic and trauma patients may be of adaptive advantage as the convalescing animal is provided with adequate energy substrates and amino acids for hepatic protein synthesis. However, if this catabolic response is prolonged the loss of body protein can pose a threat to survival by resulting in pulmonary and cardiovascular insufficiency, and impaired immune function and wound healing[26]. It is for these reasons that attempts have been made to reverse or at least slow down protein catabolism in critically ill surgical patients.

The effects of nutritional support

The optimal nutritional support of severely injured and septic patients has been the subject of intensive investigation. As such patients have a basal metabolic expenditure elevated by 20 per cent or more above normal[31] and as they can lose as much as 40 g nitrogen a day[113], they exhaust their energy and protein reserves much more rapidly than non-stressed patients. Although normal hospital food is the most efficient means of providing calories and protein to these patients, their gastrointestinal system is frequently unable to cope and intravenous nutritional support is indicated.

Septic and injured patients require approximately 40 kcal kg^{-1} per day[114] and this energy requirement has traditionally been supplied as glucose. Glucose infusion has been demonstrated to be a simple and effective means of conserving body protein in severely stressed patients[42]. However, there has been considerable interest in the role of fat as a major and perhaps preferred energy substrate in septic patients and this debate has recently been reviewed by Long[115]. We have used isotopic tracer methodology to demonstrate that lipolysis and fatty acid oxidation are enhanced in sepsis[41,43,67], but whether fat has a greater protein sparing effect than glucose in this setting is yet to be resolved[116].

Despite recent advances in intravenous nutritional support there are several reports indicating that a positive nitrogen balance cannot be achieved in septic or severely traumatized patients[2,88]. Intravenous nutrition (IVN) reduces the net rate of loss of protein by increasing the rate of protein synthesis. However, the capacity to increase synthesis by providing substrate falls short of the increased protein catabolism which proceeds uninfluenced by nutritional support[8,117].

The failure of standard IVN regimens to achieve nitrogen retention in severely stressed patients has led to the investigation of more exotic mixtures. The use of branched chain amino acids to encourage protein anabolism has received much recent attention. Branched chain amino acids play an important part in the regulation of muscle synthesis[118,119], and muscle biopsies of injured and septic patients have shown signficant increases in the intracellular concentration of branched chain amino acids[120]. It has been postulated that this may provide a stimulus for protein synthesis[97]. Series in which postoperative patients have been infused with branched chain amino acids alone[121], with branched-chain-amino-acid-enriched IVN[122] or with α-keto-isocaproate, the ketoacid breakdown product of leucine[123], have shown patients to have improved nitrogen balance, presumably on the basis of increased muscle synthesis. As yet there are no data from prospective trials to support the routine use of such modified IVN mixtures.

Pharmacological manipulation

Hormonal blockade

Several approaches have been taken in attempts to attenuate the catabolic response of severe surgical illness by hormonal blockade. Epidural anaesthesia abolishes the postoperative release of catecholamines and cortisol and has been shown to improve the cumulative nitrogen balance over a 5-day postoperative period in women after hysterectomy[124]. Using isotopic tracer methodology we have recently studied the effects of epidural anaesthesia in 23 patients who had recently undergone extensive surgical procedures[125]. There was a 20 per cent decrease in the rate of production of glucose with a parallel reduction in glucose oxidation, and net protein catabolism as measured by the rate of appearance of [^{14}C]urea was reduced by 11 per cent.

The sympathetic response may also be attenuated with specific pharmacological antagonists. Sympatholytic drugs have been demonstrated to reduce the degree of hypermetabolism in burn patients[126]. In our laboratory we have studied the effects of α and β blockade produced by infusions of phentolamine and propranolol respectively in stressed patients receiving intravenous nutrition[127]. Our data demonstrate that the role of the sympathetic nervous system in the promotion of endogenous glucose turnover in such patients is primarily a β-adrenergic effect, whereas the promotion of protein catabolism is mainly an α-adrenergic effect.

Considerable interest in the role of prostaglandins as effectors of the stress response has been aroused by the recent work on interleukin 1. However, decreasing prostaglandin synthesis with cyclo-oxygenase inhibitors does not reduce muscle catabolism in septic or thermal injury models in animals[128,129] or in septic patients[108], and their use exposes patients to side-effects such as peptic ulceration and impaired haemostasis.

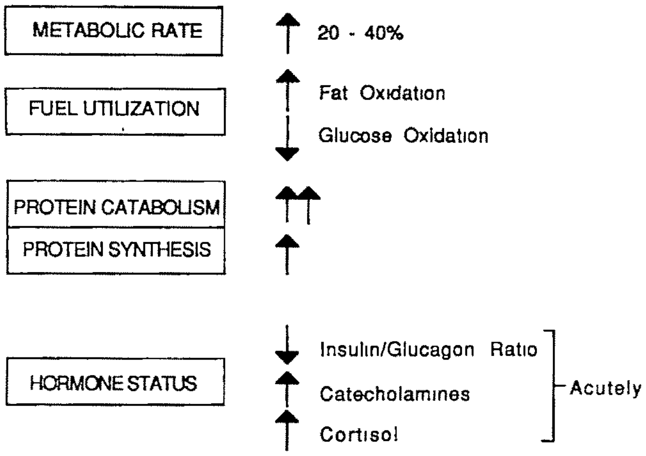

Figure 3 *Summary of the metabolic changes associated with critical surgical illness (modified from Shaw and Wolfe, 1987*[31]*)*

Anabolic hormones

The use of anabolic hormones to attenuate the rate of breakdown of body reserves is an appealing proposition. Insulin has been shown to improve nitrogen balance in trauma patients[130], but was found to have no effect on the gain of body nitrogen or fat when used as an adjuvant with a 2-week course of IVN[131]. Similarly, anabolic steroids have improved the nitrogen balance in postoperative patients[132], but have not been demonstrated to improve the efficacy of IVN[133].

Interest in the therapeutic role of human growth hormone has increased since 1985 when gene recombinant technology enabled its manufacture on a scale which makes its use as a pharmacological agent feasible. Several early investigators reported improved nitrogen balance in burn patients to whom growth hormone was administered[134–36]. More recently Ward and colleagues have demonstrated a favourable influence of growth hormone on protein kinetics in postoperative patients[137] However, the therapeutic role of growth hormone in catabolic patients awaits further definition.

Discussion (*Figure 3*)

The increased release of hormones, particularly adrenaline, glucagon and cortisol, mediate many of the metabolic changes seen in sepsis and trauma. The role of interleukin 1 has yet to be precisely defined, but there is increasing evidence that substances released from damaged tissue are at least partly responsible for the accelerated proteolysis seen in severe surgical illness.

Glucose turnover is increased in sepsis and trauma, but glucose is oxidized with reduced efficiency. There is evidence to suggest that fat is the preferred energy substrate in septic and, to a lesser degree, injured patients.

In critical surgical illness the rates of both protein synthesis and catabolism are increased. However, the increase in catabolism is of greater magnitude resulting in a net breakdown of protein and, if prolonged, muscular wasting, cardiopulmonary insufficiency and immune compromise.

The provision of sufficient energy substrates and nitrogen does not reduce the catabolic response but encourages protein synthesis, decreasing net catabolism. Numerous substrate, hormonal and pharmacological manipulations have been tried to improve the nitrogen balance in surgical patients who are severely ill. To date, the clinical efficacy of none has been conclusively proved.

Prediction of outcome in 87 patients following acute bleeding oesophageal and gastric varices due to portal hypertension from chronic liver disease was studied at our hospital over a 30-month period. The overall mortality rate was 26 per cent (23/87), with the operative mortality rate (50 per cent) being more than triple the non-operative mortality rate (14 per cent). The initial prothrombin time ratio (PTR) alone was significantly different in survivors and non-survivors both in the operated and non-operated patients. The only survivor in the whole material with a PTR $\geqslant 2{\cdot}2$ *was a patient who was transferred and underwent successful liver transplantation elsewhere. Among operated intensive care unit (ICU) patients, the Glasgow predictor gave a mean probability of discharge of 0·81 (s.d. 0·15) in 13 survivors and of 0·35 (s.d. 0·35) in the 15 non-survivors* ($P < 0{\cdot}001$)*. In the 11 non-operative ICU patients, who had failed sclerotherapy, the Glasgow predictor could not be validated. Fourteen ICU deaths were associated with significant hypotension defined as a systolic blood pressure* <90 *mmHg for* >1 *h.*

Keywords: Outcome prediction, gastric and oesophageal varices, haemorrhage

Massive bleeding from ruptured oesophageal and/or gastric varices is the main complication of portal hypertension from chronic liver disease[1]. Conservative management with the addition of sclerotherapy works well in the majority of patients[2]. A high mortality rate (50 per cent) has been reported in patients who are either unsuitable for sclerotherapy (e.g. those with gastric varices) or who have failed sclerotherapy and who require emergency surgery for the management of their acute variceal haemorrhage[3]. Severe acute bleeding from oesophageal and gastric varices forms an appreciable component of our total intensive care unit (ICU) workload. We have noticed a high mortality rate in our practice, especially in postoperative patients who were considered to require emergency surgery for the control of their bleeding gastric varices. Vast amounts of blood are frequently expended on these patients, often with little impact on outcome. We therefore felt that a reliable predictor of hospital outcome was required to assist us in deciding which patients were likely to survive an operative procedure and justify the expenditure of large volumes of blood.

The work of Garden *et al.*[4] showed that three variables: the initial prothrombin time ratio (PTR), serum creatinine and the presence or absence of encephalopathy were independently predictive and, using them in a derived regression equation, they were able to demonstrate that a probability of discharge figure of 0·66 divided the high risk from the low risk patients. They successfully predicted outcome in 90 per cent of their admissions. We compared the Glasgow predictor with the value of the initial PTR taken as soon as possible after admission to hospital. In our practice it had been our clinical impression that the degree of elevation of the PTR alone gave a good correlation with outcome in patients with acute bleeding gastric and oesophageal varices, both in operated and non-operated cases. We were also interested to ascertain if the presence of intra-operative hypotension for surgical patients and hypotension in the first 24 h of admission for medical patients was an important additional factor in determining outcome.

Patients and methods

All patients known to be suffering from acute bleeding oesophageal and/or gastric varices due to chronic liver disease admitted to the Riyadh Armed Forces Hospital over a 30-month period (March 1985–August 1987) were studied, those who required admission to our six-bedded ICU were studied prospectively, whereas those managed on the general wards were studied retrospectively. These patients constituted the entire hospital admissions of acute variceal haemorrhage during the study period. All patients had fibreoptic endoscopic confirmation of bleeding from oesophageal or gastric varices. Our initial management of these patients was conservative Routine resuscitation was performed with oesophageal tamponade when necessary The few patients requiring oesophageal tamponade in the presence of encephalopathy were routinely intubated with a cuffed endotracheal tube in the ICU

We identified two groups of patients admitted to our ICU

1 Operative patients diagnosed in the ICU or endoscopy room as bleeding from predominantly gastric varices and who were considered to require emergency surgery (variceal ligation, gastric transection and splenectomy) for the control of their haemorrhage. No patient in this series underwent a shunt operation. These patients were routinely admitted to ICU postoperatively.

2 Non-operated patients diagnosed as suffering from predominantly oesophageal varices who were managed in the ICU because of severe bleeding following failed sclerotherapy They were considered too ill to be managed on the general wards.

All ICU patients had the first recorded values of the PTR, serum creatinine and the presence or absence of encephalopathy on admission to hospital noted. Our PTR is an international normalized ratio based on a direct calibration of our thromboplastin reagent against the World Health Organization international reference preparation The upper limit of normal in our population is 1·2 A derived regression equation as suggested by Garden *et al.*[4] was utilized to estimate the probability of discharge from the three variables already mentioned

$$\ln(P/1-P)=10-(4{\cdot}3\times \mathrm{PTR})-(0{\cdot}03\times \mathrm{Creat.})-(0{\cdot}85\times \mathrm{ENC})$$

where P is the probability of discharge; ENC is $+1$ in presence of encephalopathy and -1 in absence of encephalopathy; and Creat. is the the serum creatinine in SI units

Our ICU patients also had their APACHE II score recorded on the day of admission to the unit[5] The APACHE II system is based on deviations from normal of 11 acute physiological variables including the mean systemic arterial blood pressure and the Glasgow Coma Scale. Age, defined chronic ill-health and emergency surgery were also taken into consideration The most deranged value of the 11 physiological variables but best Glasgow Coma Scale were chosen from the first day's data. Patients with a day 1 APACHE II score >35 were predicted to die[6] The APACHE II risk of death was obtained from a multiple logistic regression equation using coefficients devised by Knaus *et al.*[5] for certain specific diagnostic categories

ICU patients' blood pressures were recorded on anaesthetic charts in operative cases and these were assessed immediately after surgery to

ascertain if any significant hypotension, defined as a systolic blood pressure <90 mmHg for >1 h, had occurred. The presence or absence of significant hypotension was also noted in non-operative cases in the first 24 h of admission to the ICU. The total amount of blood given to each patient during their stay in hospital was also recorded. All patients who were operated on were given liberal quantities of fresh frozen plasma routinely during the course of surgery and other clotting factors were also administered as required. We endeavoured to find the cause of the chronic liver disease in all our patients using serological investigations in conjunction with intraoperative and/or percutaneous liver biopsies. All patients who were discharged alive from the ICU were followed up until hospital discharge or death.

The 48 patients treated solely on the general wards during the same 30-month period as the ICU series had the following data collected retrospectively: age, sex, hospital outcome details, initial PTR, endoscopic details and cause of chronic liver disease.

Predictive power of the predictive model using the PTR was calculated as follows:

$$\text{Sensitivity}=\frac{\text{PredDDead}}{(\text{PredDDead}+\text{PredADead})}\times 100$$

$$\text{Specificity}=\frac{\text{PredAAlive}}{(\text{PredAAlive}+\text{PredDAlive})}\times 100$$

$$\text{Predictive value of dying}=\frac{\text{PredDDead}}{\text{Total predicted to die}}\times 100$$

$$\text{Predictive value of living}=\frac{\text{PredAAlive}}{\text{Total predicted to live}}\times 100$$

$$\text{Correct}=\frac{(\text{PredAAlive}+\text{PredDDead})}{\text{Total patients}}\times 100$$

where PredDDead are patients who were predicted to die and died; PredDAlive are patients who were predicted to die and lived; PredAAlive are patients who were predicted to live and lived, and PredADead are patients who were predicted to live and died.

All data were collected on special forms and entered into a microcomputer (IBM AT), using a program written in dBASE III Plus (Ashton–Tate) by one of us. This was utilized to generate APACHE II scores, risks of death, probability of discharge values and for performing statistical calculations. Student's t test was used where appropriate.

Results

Out of a total of 87 adult patients with acute variceal bleeding admitted to our hospital over a 30-month period 23 (26 per cent) died. Thirty-nine patients (45 per cent) were admitted to our ICU and 48 (55 per cent) were managed entirely on the general wards. There were no readmissions to the ICU; readmissions to the ward were not taken into account in our analysis. Among the 39 ICU patients there were 18 (46 per cent) hospital deaths. The basic characteristics of these patients are shown in *Table 1*. There were 28 surgical and 11 non-surgical cases. *Table 2* shows the causes of chronic liver diseases in the ICU patients; 61 per cent of cases were caused by schistosomiasis and hepatitis B. The large preponderance of male to female patients (18·5:1) in this series can be partly explained by the higher incidence of schistosomiasis[7] and hepatitis B virus[8] among Saudi Arabian men.

The mean APACHE II scores, risks of death, the mean APACHE II blood pressure scores, the mean probability of discharge and its component variables, the presence of significant hypotension and the total amount of blood utilized by the ICU survivors and non-survivors are compared in *Table 3* for both operative and non-operative cases. In the operated ICU group the mean APACHE II scores of survivors and non-survivors were 14·6 (s.d. 3·3) and 22·5 (s.d. 9·5) respectively and mean risks of death were 19·6 per cent (s.d. 10·0) and 43·2 per cent (s.d. 26·3) respectively ($P<0{\cdot}01$ for both). Five of the 18 ICU patients who died had a day 1 APACHE II score >35 and were predicted to die.

The probability of discharge among operative ICU patients was 0·81 (s.d. 0·15) in survivors and 0·35 (s.d. 0·35) in non-survivors ($P<0{\cdot}001$). The PTR was the only variable in the Glasgow predictor that was significantly different between survivors, 1·54 (s.d. 0·20) and non-survivors, 2·1 (s.d. 0·41) with $P<0{\cdot}001$. This was reflected in the amounts of blood required by non-survivors (mean 31 units/patient) which was three times that required by survivors (mean 10 units/patient).

In the non-operated ICU group (11 patients) the mean APACHE II score among survivors was 13·8 (s.d. 5·0) and in non-survivors was 22 (s.d. 5·3) with $P<0{\cdot}05$ and mean risk of death was 28·6 per cent (s.d. 13·8) in survivors and 66·2 (s.d. 4·4) in non-survivors ($P<0{\cdot}005$). The mean APACHE II blood pressure score was 0·75 (s.d. 1·0) in survivors and 3·3 (s.d. 1.2) in non-survivors ($P<0{\cdot}01$). The Glasgow probability of discharge values were not significantly different between the survivors and non-survivors. The mean serum creatinine was 104·5 μmol/l (s.d. 56·4) in survivors and 215·5 μmol/l (s.d. 70·9) in non-survivors ($P<0{\cdot}025$). Also the PTR was 1·7 (s.d. 0·3) in survivors and 2·5 (s.d. 0·5) in non-survivors ($P<0{\cdot}01$).

The predictive value of the first PTR and the presence or absence of significant hypotension among operative and non-operative cases is analysed by histograms in *Figures 1* and *2* respectively. *Figure 1* demonstrates that all operative cases with a PTR <2·0 survived except for four patients who developed significant hypotension intraoperatively and a patient with a PTR of 1·5 who suffered no intraoperative hypotension but died on the general ward 3 weeks later from a massive rebleed. There were two patients with a PTR <2·0 who survived despite sustaining intraoperative hypotension. All ten operative ICU patients with a PTR >2·0 died with or without significant hypotension. In *Figure 2* it can be seen that significant hypotension occurred only in the three non-survivors whereas among the survivors it was not recorded. One of the patients who succumbed had a PTR <2·0; the other two who died had a very deranged PTR. Out of the total of 39 ICU patients none survived with a PTR ⩾2·2.

During the same period of 30 months, 46 patients bleeding from oesophageal varices and two bleeding from gastric varices were managed entirely on the general wards. The two gastric

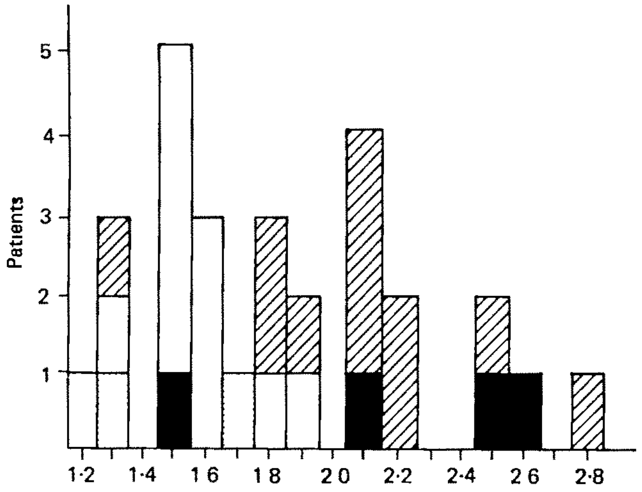

Figure 1 *Outcome of operative intensive care unit patients with acute variceal haemorrhage in relation to initial prothrombin time ratio and significant intraoperative hypotension (SIH).* □, *Alive and no SIH;* ▨, *alive and SIH;* ■, *dead and SIH;* ■, *dead and no SIH*

variceal patients had stapling of their gastric varices and splenectomy surgery for control of their bleeding. They could not be accommodated in the ICU because of an acute shortage of beds. Their PTRs were 1·0 and 1·9. They both survived their hospital stay. All the remaining 46 patients with bleeding from oesophageal varices were treated by sclerotherapy only and did not undergo surgery. Among these 48 ward-treated patients the mortality was 10 per cent (5/48). The male to female sex incidence within this ward-treated group was 8·8.1. The incidence of schistosomiasis, hepatitis B virus, cryptogenic and alcoholic-related chronic liver disease within these 48 ward-based patients was 50, 33, 12 and 4 per cent respectively. The mean age was 54·5 years (s.d. 11·3) which was not significantly different from that of the ICU patients The mean PTR of survivors was 1·43 (s.d 0·35) and of non-survivors was 4·03 (s.d. 2·89, $P<0\cdot005$). No patient within this series survived with a PTR $\geqslant 2\cdot2$ except for one patient with a PTR of 2·5 who was transferred elsewhere for liver transplantation.

Table 4 *Predicted and actual outcome for 87 patients with variceal haemorrhage*

	Predicted to live	Predicted to die	Total
Actual alive	63	1*	64
Actual dead	8	15	23
Total	71	16	87

Sensitivity	65 per cent
Specificity	98 per cent
Predictive value of dying	94 per cent
Predictive value of living	89 per cent
Proportion correct	90 per cent

* This patient underwent successful liver transplantation The predictive criterion is a prothrombin time ratio of $\geqslant 2\cdot2$

The predictive power of a PTR value of 2·2 in all the patients is shown in *Table 4*. The predictive value for dying among the 87 patients using this criterion was 94 per cent.

Discussion

Our overall hospital mortality rate from acute variceal bleeding in this series was 26 per cent (23/87) whereas the mortality rate of the 30 operative patients (50 per cent) was more than triple that of the 57 non-operative patients (14 per cent). The mortality rate of 46 per cent (18/39) among the ICU patients is within the range expected in that group of patients with acute variceal haemorrhage who require emergency surgery for control of their bleeding or who have failed to settle on sclerotherapy[3] Among the 39 ICU patients the mortality rate of the operated cases was 54 per cent, which is in close agreement with that quoted elsewhere[9] in patients bleeding from gastric varices; and of non-operated cases it was 27 per cent. The high operative mortality rate occurred despite the fact that the severity of illness, as assessed by the mean APACHE II risk of death, was greater in the non-operative group both in survivors and non-survivors, although this did not reach statistical significance. This is not surprising. As Murray and Macsween[10] have noted in the perioperative period, surgery *per se*, anaesthesia, blood loss, metabolic disturbances, and increased risk from infection may combine to precipitate hepatic failure in patients with chronic liver disease and thus fatally compromise recovery in these delicately balanced patients. In contrast the mortality rate of the 48 patients managed on the general wards was only 10 per cent. This group comprised 46 non-operative cases with bleeding oesophageal varices and two operative cases with bleeding gastric varices.

The ICU non-survivors had significantly higher mean APACHE II scores and risks of death than survivors indicating that they generally had a greater severity of illness. In fact five (28 per cent) of the total of 18 patients who died, three operative and two non-operative patients, had admission APACHE II scores >35 and were predicted to die on day 1 of ICU admission[6]. Prediction of death was not acted on in this study.

We have been able to validate the Glasgow predictor in our operative ICU patients but not in the non-operative ICU patients We have shown that the use of the initial PTR is a useful predictor in our population. All patients in this series with a PTR $>2{\cdot}2$ died with the single exception of a patient with alcoholic cirrhosis and an initial PTR of 2·5. He had a successful liver transplant. Using the criterion of 2·2 we were able to demonstrate a specificity of 98 per cent These data confirm our clinical impression that in patients with known chronic liver disease and markedly deranged liver function, as exemplified by a grossly elevated PTR (i.e. $>2{\cdot}0$), surgery should be avoided if at all possible It should be noted that our patients differed from those in Glasgow[4] in that we had less alcoholic cirrhosis (3 per cent as opposed to 70 per cent), but more cirrhosis due to hepatitis B virus (36 per cent as opposed to 7 per cent) and schistosomiasis did not feature in the Glasgow material while it accounted for portal hypertension in 38 per cent of our patients.

The reason that our mortality rate was so strongly associated with the PTR may be related to the fact that many of our patients had some form of postnecrotic cirrhosis, most of these patients show a disturbance of coagulation. Lewis *et al.*[11] have pointed out that the severity of bleeding in liver disease does not necessarily correlate with the extent of the coagulation defect. Furthermore, not all patients with advanced liver disease develop coagulation abnormalities or bleeding Thus our results should be extrapolated with caution to other populations, although they may well be applicable to other regions in the Middle East and Africa.

An incidence of bleeding gastric varices of 34 per cent among our patients is at the higher end of the range of the incidence of 3 per cent to 30 per cent reported in other series[9,12,13]. This may partly be due to the high incidence of schistosomiasis in our population which was 30 per cent (9/30) among the patients with bleeding gastric varices

This study has re-emphasized the important observation that any significant hypotensive episode will further compromise outcome in these very sick patients. The effects of hypotension are presumably due to a reduction in hepatic arterial flow from vasoconstriction and reduction in portal blood flow from reduced splanchnic perfusion. The injury is known to affect the perivenular hepatocytes[14] which undergo coagulative necrosis[15]. It is thus vitally important that if patients with known chronic liver disease require emergency operative intervention for whatever reason their blood pressure is maintained as close to normal levels as possible; all strategies directed at improving splanchnic blood flow will be very important.

We are currently testing the PTR criterion of 2·2 for patients with proven chronic liver disease and portal hypertension to ascertain if it is capable of differentiating survivors from non-survivors with a specificity of 100 per cent (i e. all patients who are predicted to die, die). Validation of the predictive power of this criterion may guide us in the future to identify those patients whose probability of survival is so poor that active treatment in the ICU or surgical intervention, without the possibility of liver transplantation, should be discontinued. This will save valuable operating time, avoid unnecessary demands on skilled personnel in theatre and the ICU, and reduce the massive drain of blood and blood products from the blood bank for use in patients who have no prospects for survival.

Acknowledgements

We would like to thank Professor James Lawrie, Director of Surgery, for his help and encouragement in the preparation of this paper and for his surgical assistance with many of the cases in this study. We also acknowledge the help and close co-operation of Dr Mohammed Karawi, Head of the Department of Gastroenterology, whose staff performed all the endoscopies and who collaborated in the care of most of the patients Dr Mohammed Karawi also kindly allowed his personal records to be perused to present the data given on the ward-based patients

Anastomotic leakage: an avoidable complication of Lewis–Tanner oesophagectomy

I. M. Paterson and J. Wong

Department of Surgery,
University of Hong Kong,
Queen Mary Hospital,
Hong Kong
Correspondence to:
Professor J. Wong

Data were collected prospectively from 159 patients undergoing Lewis–Tanner oesophagectomy for carcinoma of the lower two-thirds of the oesophagus and analysed with regard to anastomotic leakage. The 30-day mortality rate was 3·8 per cent and none of these deaths was due to anastomotic leakage. In hospital, mortality was 7·5 per cent. Six patients (3·8 per cent) had evidence of a leak. In four patients this was from the suture line, but in the remaining two it was due to patches of gangrene in the fundus of the transposed stomach and was separate from the anastomosis. Two patients died with an unhealed leak. Anastomotic leaks were minor in three instances and healed with conservative treatment but the fourth required exploration. Gangrene of the oesophageal substitute resulted in gross leakage with mediastinitis and required exploration in both cases. An apparent predisposing cause was evident in five of the six cases with leakage and some of these might have been avoidable. Transthoracic oesophagectomy can be performed with acceptably low mortality and leak rates and may therefore be considered as the treatment of choice for most patients with oesophageal cancer.

Keywords: Oesophageal neoplasm, oesophagectomy, anastomotic leakage

The prognosis of patients with carcinoma of the oesophagus is poor but treatment can provide useful palliation by restoring the ability to swallow. It is also possible to achieve 5-year survival rates of 43–54 per cent in those patients who have had resections for node negative disease[1–3]. There is, however, a widespread reluctance to submit patients to oesophageal resection because of the reported high mortality rate from many series: 20 and 33 per cent in two large reviews[4,5] respectively with the major complications being cardiorespiratory problems and anastomotic leakage. As a result many patients are treated by radiotherapy, intubation or laser which achieve inferior palliation and are attended by either less or no chance of cure. There is also controversy about the type of approach that should be used for oesophagectomy and there has been a recent trend towards transhiatal oesophagectomy without thoracotomy. It has been our preference to treat carcinoma of the middle and lower thirds of the oesophagus by oesophagectomy and oesophagogastric anastomosis using a laparotomy and right thoracotomy approach as first described by Lewis[6] and by Tanner[7]. The purpose of this paper is to highlight the low anastomotic leak rate and mortality rate which can be achieved with this type of oesophagectomy and to analyse the predisposing causes of those leakages which did occur.

Patients and methods

Between July 1982 and April 1987, data were collected prospectively from 364 unselected patients with carcinoma of the middle and lower thirds of the oesophagus who were admitted to the Department of Surgery, University of Hong Kong at Queen Mary Hospital All patients underwent surgery unless they were in the terminal stages of the disease or refused operation. The preferred method of resection and reconstruction was the Lewis–Tanner oesophagectomy which had been modified so that the oesophagus was resected to the apex of the thorax[8]. Transhiatal oesophagectomy was reserved for patients with diminished pulmonary reserve Colon or jejunum was only used as the oesophageal substitute when the stomach was diseased or had previously been resected The 159 patients who had a Lewis–Tanner oesophagectomy form the basis of this study. There were 141 men and 18 women with a mean age of 60 years Only one tumour was an adenocarcinoma, the remainder being squamous carcinomas. Seventy-eight patients (49 per cent) were considered to have had a potentially curative resection while 81 (51 per cent) had the resection for palliation only.

At operation, an upper midline abdominal incision was used and the stomach completely mobilized preserving whenever possible the right gastric as well as the right gastroepiploic vessels. Seventy-nine of the patients had a pyloroplasty, three had pyloromyotomy and 77 had no gastric drainage procedure. Right thoracotomy was then performed through the fifth interspace and the oesophagus resected together with a mediastinal node dissection. Distally the stomach was transected just below the cardia while the proximal line of transection was at the apex of the right chest An oesophagogastric anastomosis was made between the oesophagus and the posterior wall of the fundus of the stomach A circular stapler was used if possible and the largest size which would fit into the oesophageal lumen was chosen[9] An EEA stapler (US Surgical Corporation and Auto Suture UK, Ascot, UK) was used in 62 cases and an ILS stapler (Ethicon Ltd , UK) in 88 cases Nine patients had an anastomosis performed with a single layer of continuous, absorbable suture when the oesophagus was too small to admit a stapler.

Radiological contrast swallows were not routinely performed since an earlier study showed them to be of no clinical value and potentially dangerous[9] We have, however, adopted an aggressive approach towards excluding leaks in patients who have evidence of sepsis. If a leak was suspected,then a Gastrografin (Schering AG, Berlin, FRG) swallow or endoscopy was used to establish the diagnosis In two cases thoracotomy was performed without prior confirmation of a leak because there was evidence of severe mediastinal contamination

Results

Of the 159 patients in this series, six (3·8 per cent) died within 30 days of the operation but none of these deaths was related to anastomotic leakage. Another six patients died up to 5 months after their operation without being discharged from hospital giving a total hospital mortality rate of 7·5 per cent. The causes of death in these patients were: bronchopneumonia (three), anastomotic leakage (one), septicaemia due to subphrenic abscess (one) and cerebral metastasis (one).

Six patients (3·8 per cent) had evidence of leakage. In four of the patients the leakage was from a staple or suture line but in the other two the defect resulted from a patch of gangrene in the fundus of the stomach which was separate from the anastomosis.

0007–1323/89/020127–03$3.00 © 1989 Butterworth & Co (Publishers) Ltd

A predisposing cause could be identified in each of the four patients with an anastomotic leak. Two of the patients required a thoracotomy for postoperative bleeding within 2 days of their oesophagectomy. One patient who did not have a gastric drainage procedure developed gastric outlet obstruction with gastric distension before the leak became apparent. In the fourth patient the leak was not directly from the oesophagogastric anastomosis but from a longitudinal tear in the oesophagus above the line of resection This had been recognized and repaired at the original operation and was attributed to rigid oesophagoscopy performed immediately before the operation. In three of the patients the leak produced minor evidence of sepsis (pyrexia $<38°C$, no evidence of pleural effusion or shock) and the diagnosis was made endoscopically. These were treated conservatively and healed. The fourth patient required exploration and drainage, healing did not occur and the patient died 33 days postoperatively.

Both patients who had patches of gangrene in the fundus of the stomach developed clinical features of gross mediastinal contamination with high fever, hypotension and pleural effusion. Thoracotomy was performed for pleural toilet, to establish drainage and to attempt repair of the defect, but this was unsuccessful in one and the leak persisted until the patient died 5 months later The latter patient had required a laparotomy for small bowel herniation into the chest 2 days after oesophagectomy and had a period of hypotension at this time

The development of leakage did not appear to be related to the method of anastomosis chosen: three by EEA stapler, two by ILS stapler and one by hand. None of the six patients received preoperative radiotherapy

Discussion

Oesophagectomy can only be considered a useful form of treatment for carcinoma of the oesophagus if the morbidity and mortality rates of the procedure are low. There is also controversy about the type of oesophagectomy and anastomosis that should be employed in order to minimize these risks. A major disadvantage of transthoracic oesophagectomy in the past has been the high mortality rate which was largely due to anastomotic leakage. This was highlighted in the review by Earlam and Cunha-Melo who reported an overall mortality rate of 33 per cent[5]. Recently, much improved mortality figures have been reported which might be attributable to the very low anastomotic leak rates (0–3·5 per cent) that can be obtained with the circular stapler[10–13] Good results have also been obtained with a sutured anastomosis. Akiyama *et al.*[3] have reported a mortality rate of 1·4 per cent and a leak rate of 5·2 per cent, while Huang *et al.*[2] in a large study of 1647 cases were able to achieve mortality and leak rates of 4·1 and 4·5 per cent, respectively. A previous report from this unit failed to show any difference in leakage between an anastomosis by hand and by stapler, although the latter produced a higher incidence of postoperative stricture[9]. The anastomotic leakage rate of 2·5 per cent and overall leak rate of 3·8 per cent in the present series compares favourably with those quoted above despite an aggressive policy of surgical treatment—76 per cent of unselected patients underwent operation and 63 per cent had a resection.

One of the stated advantages of transhiatal over transthoracic oesophagectomy is that, given a high anastomotic leak rate, the consequences of a leak in the neck are less than in the mediastinum. However, this becomes relatively unimportant if the incidence of anastomotic leakage is low. Since the proximal line of resection is similar in the two methods if the oesophagus is resected transthoracically to the apex of the chest[8], the major differences remaining between the two approaches are the relative risk of postoperative cardiorespiratory problems, and the merits of performing a blind or visualized mediastinal dissection. Argument regarding the first point is unresolved, although one non-randomized comparison has suggested that it may be higher after transhiatal oesophagectomy[14]. The risk of uncontrolled bleeding or bronchial damage using the transhiatal approach is considerable[15] and the incidence of mediastinal recurrence high[16]. We feel therefore that the present trend towards the use of the transhiatal route in most cases is not justified.

Analysis of those leaks which did occur in the present series reveals that the majority may have been avoidable. Two patterns of leakage are evident. those characterized by suture or staple line dehiscence and those due to gangrene of the oesophageal substitute Of the four patients who leaked from a suture line all had a possible predisposing cause. One was unusual in that the leakage occurred from the site of oesophageal perforation following preoperative rigid oesophagoscopy and this resulted in the only death due to an anastomotic leak. The three other cases were diagnosed endoscopically and since they were minor were treated conservatively with a successful outcome. Hypotension and haematoma around the anastomosis may have been precipitating factors in the two patients who required an emergency thoracotomy for bleeding within 2 days of their oesophagectomy. A prolonged period of postoperative gastric distension may have resulted in the fourth leak by putting excessive tension on the anastomosis A gastric drainage procedure had not been performed but the use of this as routine after oesophagectomy has been controversial. The morbidity associated with a pyloroplasty however is low and since it is impossible to predict accurately which patients will have delayed gastric emptying postoperatively it may be safer to do this in every case[17].

The distinction between anastomotic leakage and ischaemia of the oesophageal substitute may be a fine one but differences in the degree of contamination and hence clinical presentation and type of treatment required are evident. Both patients with gangrene of the stomach in this series developed mediastinitis. When the area of necrosis is large, resection of the substitute with cervical oesophagectomy and feeding gastrostomy or jejunostomy will probably be required. However, if the area of necrosis is limited, excision and repair may occasionally be possible but selection of these cases is important—primary repair was attempted in both our patients but was successful in only one. The distinction also emphasizes the need to preserve a good blood supply to the oesophageal substitute and to avoid episodes of hypotension or hypoxia, particularly in the early postoperative period. Such a predisposing cause was identified in one of the two patients since there was a period of hypotension before emergency laparotomy 2 days after oesophagectomy.

There are conflicting views as to the measures which should be taken to preserve the blood supply to the transposed stomach. All authors agree that the right gastroepiploic vessels must be preserved. The right gastric vessels can probably be divided at their origin in the majority of cases but the risk of this has not been quantified and our own practice is to preserve them if possible. Akiyama[18] leaves the antral portion of the right gastric artery, excising the first three branches of the left gastric artery with the proximal half of the lesser curvature, but stresses the importance of preserving the intramural vascular network. McKeown[19], however, feels that the entire vascular system along the lesser curve should be kept intact and therefore ligates and divides the left gastric artery flush at its origin. There is no firm evidence to favour any one of these practices.

In conclusion, on the basis of these results it would appear that anastomotic leakage may be largely an avoidable complication and the overall mortality rate in the present series was low, further improvement should be the goal.

Chylothorax and delayed paraparesis in an infant following improper use of a front seat belt

J. H. E. Laing and L. Spitz

Hospital for Sick Children, Great Ormond Street, London, UK

Correspondence to: Mr H. Laing, Department of Surgery, Orthopaedic Surgery, Brook General Hospital, London SE18, UK

Traumatic chylothorax and spinal cord injury due to blunt trauma are both very uncommon lesions in infants[1-3]. Such a case, following the incorrect use of a car seat belt, is reported.

Case report

A healthy 7-month-old male infant was being breast-fed in the front passenger seat of a motor car. The child was held inside the diagonal strap of the seat belt, which lay across his right chest and back. The front of the car struck a stationary vehicle at approximately 60 m.p.h. Mother and child were thrown forwards against the seat belt.

There was no loss of consciousness but the child became pale and cyanosed and, on admission to hospital, was cold, tachycardic and hypotensive (BP 40/20 mmHg). Chest X-ray showed a left-sided pleural effusion and 100 ml of blood was aspirated. Following resuscitation with blood and plasma he was able to commence breast-feeds.

Within 8 h he developed progressive respiratory embarrassment. A further 50 ml of blood was aspirated from the left pleural cavity and 75 ml of milky fluid from the right pleural cavity. Examination revealed signs of recurrent bilateral pleural effusions, but there was no evidence of intra-abdominal injury and a full neurological examination was normal. Bilateral basal chest drains were inserted, the left draining bright red blood, the right draining chyle (triglyceride 19·5 mmol/l). He was intubated and positive pressure ventilation instituted. Total parenteral nutrition (TPN) was commenced using a standard regimen. His condition improved and mechanical ventilation was discontinued on the fourth day, at which time medium chain triglyceride feeds were introduced. TPN was discontinued 24 h later, as the chylous effusion had reduced to minimal volumes.

Six days after admission he developed bilateral flaccid paraplegia but with retention of normal anal and bladder tone. X-ray of the cervical, thoracic and lumbar spine and computerized tomography of the brain and cervical spine were normal.

A myelogram showed no evidence of spinal cord compression, but there was leakage of contrast medium from the theca at D8–10 level. The contrast medium filled a widened epidural space on the left and leaked out through the intervertebral foramina (*Figure 1*).

Medium chain triglyceride feeds were continued for 2 weeks after which breast-feeding was restarted. There was no reaccumulation of the chylothorax. Six months after the injury he has regained partial use of his lower limbs and is otherwise well.

Discussion

Right-sided traumatic chylothorax, in the absence of bony or penetrating injury, is very uncommon and is probably due to the shearing action of the right crus of the diaphragm acting upon a thoracic duct which was distended following a fatty meal[4]. Just above the diaphragm the duct lies on the anterior surface of the vertebral column posterior to the oesophagus, and the likely mechanism of injury is hyperangulation of the spine[5].

The use of parenteral nutrition and medium chain triglyceride feeds in the management of chylothorax is based on the observation that while long chain fatty acids are absorbed into the intestinal lymphatics and hence into the thoracic duct to form chyle, short and medium chain fatty acids pass directly into the portal circulation[6]. It is occasionally necessary to ligate the duct at the diaphragm if conservative management fails[7].

The paraplegia observed in this child is most unusual and was probably associated with the dural tear observed on the myelogram. Spinal cord injury in children may occur without any associated vertebral injury. The delay in onset of neurological signs in the absence of spinal cord compression is suggestive of an ischaemic aetiology[8]. It is noted that the arteria radicularis magna (of Adamkiewicz) enters the cord close to the level of the dural tear. This vessel arises from the lower left intercostal vessels in 80 per cent of cases, and damage to these vessels may result in ischaemic paraplegia[8,9]. Longitudinal

0007–1323/89/020129–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

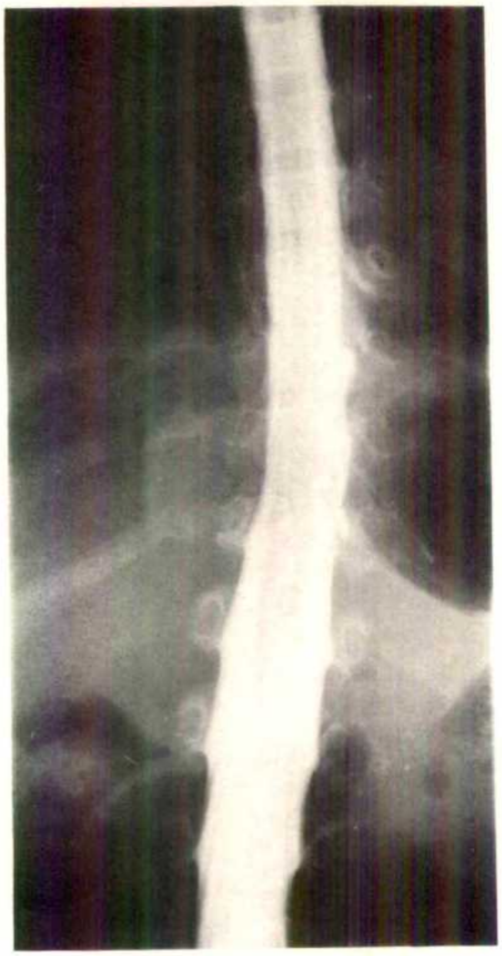

Figure 1 *Myelogram showing leakage of contrast medium from dura, and the position of the artery of Adamkiewicz*

traction to the spinal cord can cause infarction of the conus in this manner[7,8].

We postulate that hyperangulation of the lower thoracic spine over the seat strap resulted in a tear in the thoracic duct on the right causing chylothorax, and an avulsion injury to the artery of Adamkiewicz or its tributaries on the left causing an ischaemic cord injury.

The use of seat belts has been shown to reduce the severity of injury to adults in motor vehicle accidents, and the use of approved child restraints to reduce child mortality[10]. Following legislation in 1983 enforcing the use of front seat belts, over 95 per cent of adults now comply. Since only 25 per cent of the population use child restraints, the illegal carriage of children inside front seat belts with adults is probably common, and in the event of an accident may result in severe injuries to the child[11]. The risks should be widely publicized, and the use of approved child restraints encouraged.

Gastroplasty for morbid obesity: technique, complications and results in 60 cases

E. R. T. C. Owen,
R. Abraham* and
A. E. Kark

Departments of Surgery and
**Dietetics, Northwick Park Hospital*
and MRC Clinical Research Centre,
Harrow, Middlesex, UK

Correspondence to:
Mr E. R. T. C. Owen, Academic
Surgical Unit, St. Mary's Hospital,
Praed Street, London W2 1NY, UK

A series of 60 gastroplasty operations based on Mason's vertical banded procedure are described. Details of technique, modifications, complications and results are discussed. Operative treatment results in a reduction to within 40 per cent of ideal weight in 80 per cent of patients between 12 and 18 months after surgery. The constricting band should not be greater than 5 cm; if it is most procedures will fail after 18 months. Pouch size should be measured and made no greater than 20 ml. The importance of nutritional counselling is emphasized. The surgical treatment should form part of a multidisciplinary approach with careful selection and long-term follow-up.

Keywords: Gastroplasty, morbid obesity, surgical technique, complications, weight loss, band size

Gastric reduction procedures have been shown to produce impressive short-term results in the treatment of morbid obesity[1,2]. Vertical banded gastroplasty or one of its modifications is the most widely used technique[3,4]. These stomach operations have almost entirely superseded small intestinal bypass operations which cause disabling metabolic disturbances[5]. While the single most obvious effect is weight reduction with its concomitant physical and social benefits, much less is understood about the causes of persistent severe obesity, the effects of gastroplasty on body composition[6], or the behavioural factors underlying gross overeating.

The earlier methods of gastroplasty failed largely because of pouch enlargement and inappropriate dietary supervision. We document here the results and complications in a series of 60 patients undergoing vertical banded gastroplasty with emphasis on the technical factors necessary for long-term successful weight loss and the importance of regular medical and dietary supervision to maintain long-term alteration in eating habits.

Patients and methods

Since 1983, 60 patients (aged 18–56 years, mean 38·8) have undergone vertical banded gastroplasty as a primary operation for weight loss (*Figure 1*). All had unsuccessfully attempted numerous dietary and group therapy regimens. All were morbidly obese, i.e. they were either at least twice ideal body-weight or more than 45 kg overweight, having been so for 5 years or more, and all suffered the debilitating morbidity of gross obesity.

All patients demonstrated the triad of symptoms: joint pain (back, hip and knee), increasing breathlessness after minimal physical exertion, and increasing social and psychological disabilities. In addition many complained of biliary symptoms, early diabetes, hypertension, loss of energy and depression. More rarely sleep apnoea occurred[7,8]. We relied on an experienced nurse counsellor, a dietitian and a lay support group to act as an additional screen to assess the stability of family background and the less easily defined attributes of perseverance and motivation. Any tendency to alcoholism or past psychiatric disorders was considered an absolute contraindication to surgery.

All patients underwent routine haematological and biochemical studies, liver function assessment and gallbladder ultrasound, chest X-ray, ECG and comprehensive pulmonary function tests, including arterial blood gas levels. In addition most patients underwent preoperative upper gastrointestinal barium studies and/or endoscopy.

Operative technique

The technique to be described was used in all patients except that: (a) the pouch size was estimated in the first 24 cases and then accurately measured in the last 36; and (b) the outlet band was initially 5·5 cm Marlex® (C.R. Bard Inc., Massachusetts, USA) but in the past 2 years a 4·5 cm or 4·75 cm GORE-TEX® (W. L. Gore and Associates Ltd., UK) band has been used (see Discussion).

Subcutaneous heparin and an H_2 receptor antagonist were administered with the premedication and a peroperative broad-spectrum antibiotic was given. Through an upper midline incision the fat is split by manual traction. A Goligher frame retractor is essential and we have designed a set of special rib retractors attached to it[9]. The oesophagogastric junction is mobilized and taped. The lesser sac is opened, all adhesions to the pancreas up to the level of the oesophagus are divided and the posterior margin of the lesser curve cleared along its length. The lesser omentum is opened at this level hard against the lesser curvature to avoid vagus and venous branches. A large 32 Ewald tube is passed into the stomach by the orogastric route. A point is marked 5 cm down from the oesophagogastric junction and 5 cm in from the medial edge of the lesser curve by a Babcock forcep. At this point a Hearn needle[10] attached to the EEA instrument (Auto Suture Company, Ascot, UK) is pushed through both walls of the stomach. The EEA instrument is positioned so that the rim of staples abuts against the tube, and is closed to excise and staple a 28 mm window which is then oversewn with a 2/0 linen continuous suture. A linear stapler (55, 60 or 90 mm) is then passed through the window to emerge at the oesophagogastric junction and positioned to lie parallel to the lesser curve. After temporary closure of the stapler the Ewald tube is withdrawn into the lower oesophagus and a fine-bore nasogastric tube is introduced; two soft enterostomy clamps are placed, one across the oesophagogastric junction and the other across the distal opening of the pouch (*Figure 2*). The aim is to create a pouch with 10–20 ml capacity at a pressure of 25 cmH_2O by adjusting the position of the

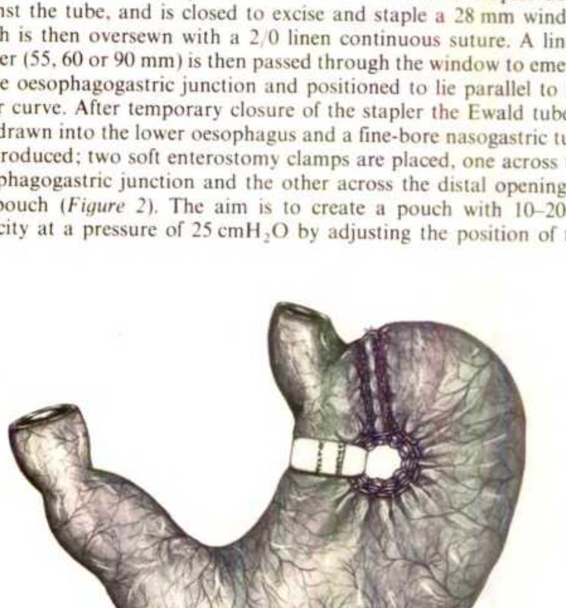

Figure 1 *Completed vertical banded gastroplasty (adapted from Flejou* et al.[25])

stapler. The staples are then fired using a double cartridge with four staple lines or two parallel applications of a single cartridge. The staple line is reinforced anteriorly by silk sutures to prevent strain and separation of the staple line (*Figure 1*). The integrity of the pouch is tested by instilling methylene blue via the narrow nasogastric tube with two soft clamps in place (*Figure 2*). A 6 cm strip of GORE-TEX 1·5 cm wide is placed around the pouch exit (*Figure 1*) so that 1·25 cm overlaps making a 4·75 cm circumference band. This is fixed by interrupted GORE-TEX sutures with the large Ewald tube in place to avoid narrowing. Omentum is brought over to cover the GORE-TEX. Cholecystectomy is then done if deemed necessary. Abdominal closure is secured by one layer of looped continuous No. 1 monofilament nylon followed by subcuticular Prolene® (Ethicon Ltd., Edinburgh, UK). The peritoneal cavity is not drained and no nasogastric intubation is used.

The patient is extubated in a sitting position, which is maintained in a chair during the first 6–8 h postoperatively. Chest physiotherapy and mobilization is started immediately and repeated two or three times a day, and a subcutaneous morphine pump infusion (2–5 mg/h) provides adequate analgesia and allows good lung expansion. The first 31 patients were managed in the intensive care unit postoperatively for 24 h. This has been found to be unnecessary and patients are returned to the ward where nursing staff are familiar with the procedure.

H_2-receptor antagonists are given intravenously and then orally after day 1, and subcutaneous heparin is continued until full mobilization after 4–5 days. Fluids are encouraged from the first day and small amounts of purées by days 2–3. Discharge is arranged by the fifth or sixth day and sutures removed later as an outpatient. Within the early postoperative weeks a barium study is done to provide a baseline measurement of the size of the gastric pouch and outlet.

Postoperative dietary management must ensure a 3200 kJ nutritional intake which permits a safe weight loss[11]. Full fluids are continued for 4–12 weeks including small quantities of soup, jelly and drinks. When purées are started a pint of skimmed milk per day is recommended to provide the appropriate energy intake. A mineral and vitamin supplement makes up the nutritional deficit that has been demonstrated on these diets[12,13]. Solids are slowly introduced after 2–3 months and it is largely texture and not quantity that alters at this stage.

Statistical methods

Body-weight was expressed as a percentage of the ideal weight. Ideal weight was taken as the maximum weight for height and calculated using Quetelet's index ($\text{weight} \div \text{height}^2 = 25$). Patients were assessed and weighed at regular intervals postoperatively: monthly for the first 6 months, 3-monthly for the next 6 months, and 6-monthly after this. At 6-monthly intervals the change in the percentage ideal body-weight was calculated. For each 6-month postoperative period up to 2 years, an analysis of variance was performed to compare the mean change in this percentage for the four band sizes. A further comparison was done at 3 years. Weight changes after revision were excluded. The band size of 5·5 cm was then compared with the mean of the other three band sizes using the pooled estimate of standard deviation from the analysis of variance.

As the aim of any treatment for obesity is loss of the patient's excess weight we have used percentage excess body-weight to show the weight loss postoperatively (*Figures 3–6*). This is calculated by subtracting 100 from the percentage ideal body-weight and is the method recommended by a consensus of the American Society of Bariatric Surgeons for expressing the results of obesity surgery. There are no standard criteria for assessing the success of these operations in terms of weight loss but it is generally accepted that if the patient's weight reduces to a level within 40 per cent of their ideal weight (140 per cent ideal body-weight or 40 per cent excess weight) then most of the obesity-related health hazards will be circumvented and the operation can be considered a success, provided the weight loss can be maintained.

Results

Complications

Mortality. There were no hospital deaths but two patients died at home 40 and 45 days after operation. In both cases, death was due to autopsy-proven pulmonary embolus.

Gastric bleeding. Bleeding occurred in one case, requiring re-exploration of the stomach. No local lesion was found and the cause appeared to be widespread gastritis which responded to further conservative treatment and H_2-receptor antagonists.

Leaks. One leak was detected by methylene blue peroperatively and this was immediately repaired. There were no postoperative leaks.

Wound infection. Six patients (10 per cent) developed major wound infections and one developed wound dehiscence, 6 weeks

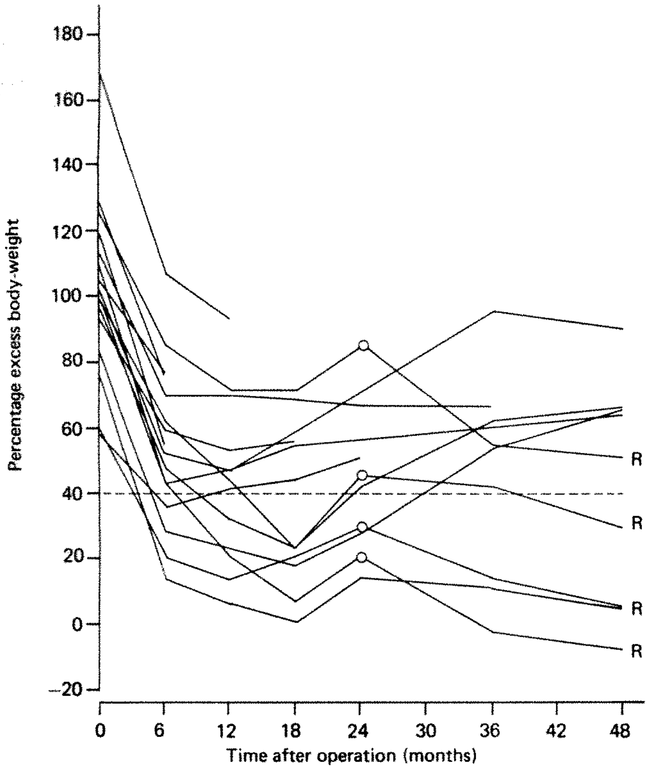

Figure 3 *Postoperative change in percentage excess weight up to 4 years in patients with a 5·5 cm band. Four patients underwent revision (R). The aim is for the patient to reduce weight so as to be within the 40 per cent (---) excess weight level (140 per cent ideal body-weight).* ○, *Revision date. One patient in this group died and is not included in the figure*

later while at home. Twenty-four (40 per cent) had minor serous discharge and 17 (28 per cent) of these had positive cultures (13 with *Staphylococcus epidermidis*). Concurrent cholecystectomy in nine patients resulted in one case of major sepsis. There has been one case of incisional hernia to date.

Thromboembolism. One patient developed venographically confirmed deep vein thrombosis and suffered a non-fatal pulmonary embolus, in addition to the two fatalities above.

Chest infection. There were eight cases (13 per cent) with purulent sputum and a positive culture. Six had mucopurulent sputum and a normal flora. Eight cases (13 per cent) of atelectasis were noted on X-ray but the patients were otherwise asymptomatic. Only one patient was electively ventilated for 24 h because of her shortness, kyphosis and extreme obesity.

Staple line dehiscence. Four patients (7 per cent) developed staple line dehiscence (diagnosed by barium meal and endoscopy), one at 6 weeks and the others after 1 year. Two of these patients had developed concomitant stomal stenosis (see below).

Stomal stenosis. Five patients (8 per cent) developed stenosis, one at 3 months and four after 1 year.

Band erosion. One patient developed band erosion 2 years after operation in which a Marlex band was used. This patient had a coexistent stomal stenosis and staple line dehiscence. She stabilized her weight after 6 months and maintained this for 2 years so that no further action has been taken.

Pouch size was estimated in the first 26 cases to be 30–50 ml; 17 had a band of 5·5 cm and nine a 5 cm band. The remaining 34 patients have had accurate volumetric pouch measurement of 10–25 ml. The outlet bands in this group were fashioned in three sizes: 4·5 cm (21 cases, mean pouch volume 16·4 ml, s.d. 5·4), 4·75 cm (12 cases, mean volume 18·1 ml, s.d. 4·4), and 5 cm (one case, volume 10 ml). The postoperative change in percentage excess weight for each patient is shown in *Figures 3–6*.

In the 5·5 cm band group (*Figure 3*) nine of the 17 patients have been followed for 4 years; four have needed revision because of significant weight regain owing to failure of gastric restriction, four are regaining weight and only one has stabilized at 20 per cent above ideal weight. The remainder have failed to attend follow-up. Thus nearly 50 per cent of this group are known to have failed in terms of their response to surgery.

In the 5·0 cm band group (*Figure 4*) eight of ten patients have stabilized to within 40 per cent of their ideal weight and have so far maintained this for 2–3 years postoperatively. One other patient in this group has stabilized to within 80 per cent of her ideal weight but this represents a loss of 50 per cent of her excess weight and she has maintained this with good effect.

In the 4·75 cm band group (*Figure 5*) 11 of 12 patients have lost weight; of these two stabilized by 12 months at 10 per cent and 30 per cent above ideal weight. Nine are still losing weight and one has failed having regained all her lost weight after 12 months due to total dietary non-compliance.

In the 4·5 cm band group (*Figure 6*) all patients have lost weight; most patients have been followed for between 12 and 18 months and 18 have stabilized. Eight have stabilized at or near ideal weight, five at a level of 20–40 per cent excess weight and three at 40–60 per cent excess weight. Two have regained a small amount of weight. One patient aged 56 weighing 153 kg (170 per cent excess weight) does not appear to have done well: in fact she has lost almost half her excess weight (50 kg) and her life has been transformed; she is active, mobile and able to function normally compared with her previous room-bound existence.

Statistical analysis

There were no significant differences in weight loss for patients with different band sizes at 6, 12 or 18 months postoperatively.

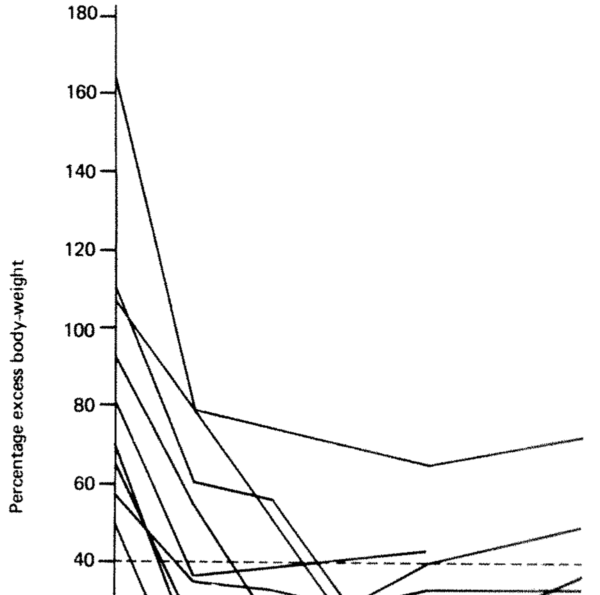

Figure 4 *Postoperative change in percentage excess weight up to 3 years in patients with a 5·0 cm band. ---, Forty per cent excess weight level. (One patient was lost to follow-up)*

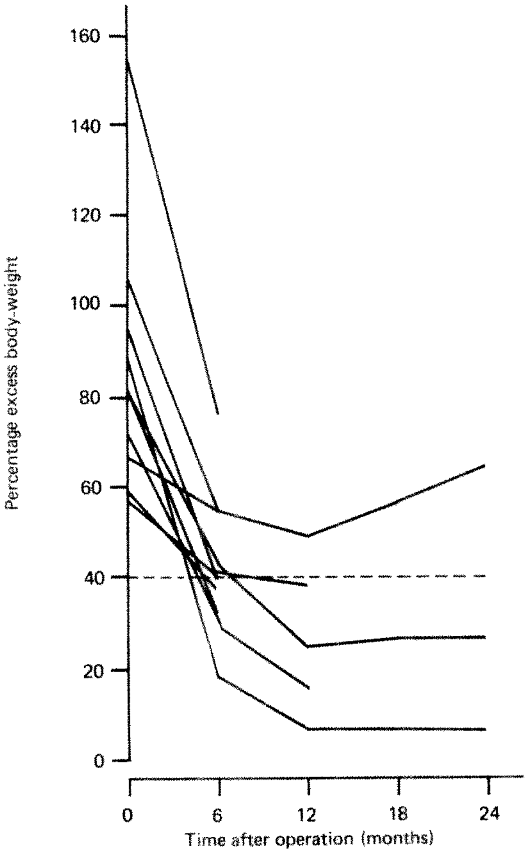

Figure 5 *Postoperative change in percentage excess weight up to 2 years in patients with a 4·75 cm band. ---, Forty per cent excess weight level. Two patients have not been included because postoperative follow-up was for <6 months*

However at 24 and 36 months the 5·5 cm band performed significantly less well than the other bands ($P = 0{\cdot}008$ and 0·05 at 24 and 36 months respectively). There was no significant difference between the 4·5, 4·75 and 5·0 cm bands at 24 and 36 months.

Figure 7 shows the change in percentage ideal weight during each 6-month period postoperatively. The mean and 95 per cent confidence intervals are shown for each band size. Zero represents no change in weight. Points above the zero line (minus figures) indicate weight loss and those below weight gain. Wherever the confidence interval for any 6-month period does not include the zero line there has been a significant gain or loss in the mean weight of the group. From *Figure 7*, it can be seen that patients with all band sizes lose a large amount of weight in the first 6 postoperative months. In the next 6 months all groups continue to lose weight but much more slowly. Weight stabilization occurs by 18 months. At 24 and 36 months the 5·5 cm band group regains weight (confidence intervals below and not including zero) whereas the other groups remain stable (confidence intervals include zero).

Discussion

The creation of a small proximal gastric pouch has been shown to be an effective method of weight reduction. The original method consisted of a horizontally stapled or sutured pouch with a Roux-en-Y or loop drainage. This constituted a major technical exercise with all the risks of gastrojejunal suture lines[14]. Thereafter a horizontally stapled pouch with a central or lateral gastrogastrostomy drainage stoma of 10 mm was developed[15], a much simpler technique which we adopted in a group of 20 morbidly obese patients. Within 18 months it was apparent that weight loss was unsatisfactory in the majority and the method was abandoned. The failure related directly to imprecise pouch size construction and continuing distension of an over-large pouch. Additionally the importance of regular

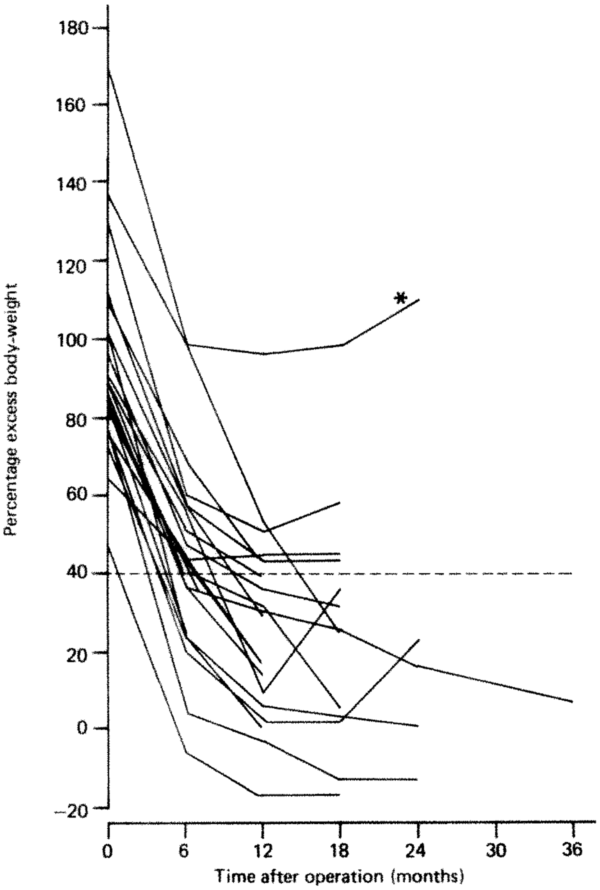

Figure 6 *Postoperative change in percentage excess weight up to 3 years in patients with a 4·5 cm band. ---, Forty per cent excess weight level. * A 56-year-old patient weighing 153 kg (170 per cent excess weight), who does not appear to have done well, in fact, lost half her excess weight and the operation was considered successful. One patient in this group died and is not included in the figure*

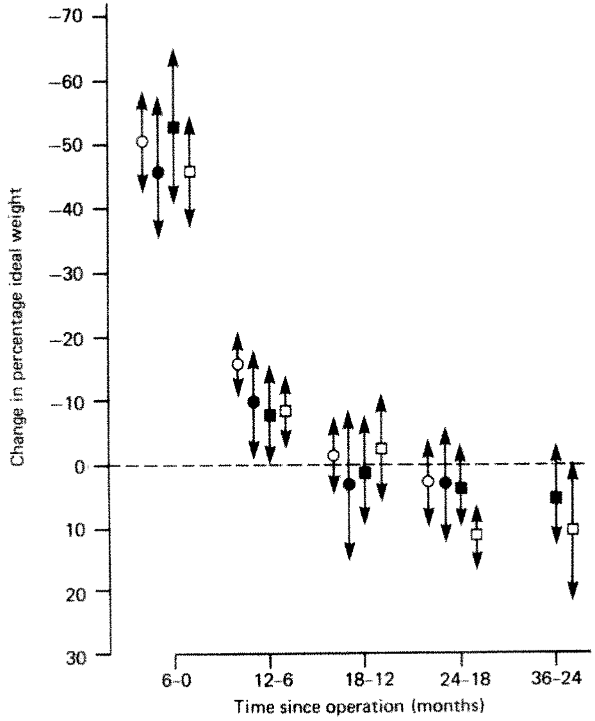

Figure 7 *Comparison of weight loss between patients with the four bands using postoperative change in percentage ideal body-weight at 6-monthly intervals up to 2 years and then at 3 years. The mean and 95 per cent confidence intervals are shown for each group. Zero represents no change in weight, i.e. stabilization of weight loss. All groups stabilize by 18 months. At 2 and 3 years, patients in the 5·5 cm group are regaining weight.* ○, *4·5 cm band;* ●, *4·75 cm band;* ■, *5·0 cm band;* □, *5·5 cm band*

postoperative supervision by a trained dietitian over many months was not fully appreciated.

Therefore we adopted the Mason vertical banded gastroplasty technique[3], with modifications described in detail above, which we believe are necessary for its success. These include accurate measurement of pouch size which is known to be grossly inaccurate if estimated[16,17]. Furthermore size varies with pressure and we have chosen to measure volume at a pressure of 25 cmH_2O.

Double staple line partitioning minimizes the risk of staple line dehiscence[18] and the double cartridge instrument is recommended[19]. Little is known about gastric staple line healing which is thought to take place in 4–6 weeks but may take as long as 3 months. It is important to prescribe liquids only for the first 6 weeks and preferably for 3 months if the patient is compliant and taking in sufficient calories; overfilling with purées and semisolids in the early postoperative weeks may well cause damage and early staple line dehiscence[20], which can be diagnosed only by barium study and endoscopy.

Serosal reinforcement of the circular staple window in the stomach is recommended to minimize leakage (nil in this series), and the integrity of the pouch and staple line should be tested by methylene blue instillation.

The importance of band size measurement is made clear when comparing the failures of 5·5 cm external circumference bands with the success of those of 4·5–5·0 cm. Mason has confirmed that 5·5 cm bands will eventually fail[1,21]. We have reoperated on four patients in this category and have made a new small 15 ml pouch with a 4·75 cm band, and all patients have had long-term success[22,23]. We now fashion a 4·75 cm band as the risk of stenosis is higher when the band is made tighter.

The incidence of stomal stenosis is reported to be in the region of 20 per cent[24]. However as the inability to take solid food often continues for up to 6 months, further investigation is necessary only if this persists longer. Of our five cases of stomal stenosis three have required dilatation: two needed two dilatations and one subsequently needed a pouch-gastrostomy by side-to-side anastomosis which in 2 years was followed by a small weight gain. Two patients who had stenosis did not require dilatation; the reason for this became apparent at endoscopy which showed staple line dehiscence.

The most common complication in hospital is early vomiting caused by a rushed intake; it rapidly resolves if intake is restricted for 24 h. Liquidized or puréed foods after 1–2 months reduce the likelihood of obstruction of the stoma and avoid vomiting and the risk of staple line dehiscence.

Specific food intolerances are common postoperatively especially for red meat, bread and fruit. Constipation is also common and is due to inability to take dietary fibre. The rapid early weight loss is because a very low calorie diet is inflicted on the patient and it is important that the patient does not approach near-starvation calorie levels—hence the need for close supervision by a dietitian to avoid the hazards of excess lean tissue loss and to attain a slow, sustained weight loss over 9–12 months with stabilization thereafter to near-ideal weight levels.

A gastroplasty self-help group has proved invaluable especially for new candidates for operation as well as those under regular postoperative follow-up. It is particularly helpful for spouses and closely related family members to attend. Questions of diet, clothing, daily exercise and social problems of family readjustment are discussed.

We conclude that the surgical treatment of morbid obesity by vertical banded gastroplasty is an effective means of producing successful long-term weight reduction and social rehabilitation. The long-term aim is dietary modification and the operation is the initial treatment, undertaken only after prolonged preoperative assessment. There is no long-term information available on the pouch size after 5–10 years. The very small initial pouch size of 10–20 ml provides a long time lag before any expansion takes place. By that time it is hoped that diet and eating habit modifications should be firmly established.

Acknowledgements

Our thanks are due to Ms Caroline Dore, acting head of the Division of Statistics, Clinical Research Centre for statistical advice and analysis; Nigel Webb for medical illustrations; Mrs Anita Gurmin and Miss Lesley Wooldridge for preparation of the manuscript. We are especially grateful to Sister Pauline Hamblin, nurse counsellor, who assisted in assessment and postoperative dietary supervision.

Professor B. Husemann

From 1 January 1969 until 31 December 1985, gastric resections were performed in 937 patients with carcinoma of the stomach and 422 patients with carcinoma of the cardia. During this period, the general frequency of cardia carcinoma increased continuously from 6·6 per cent (1969–71) to 37·5 per cent (1984–85) and a corresponding decrease of carcinomas in other sites was observed. Early carcinomas (pT1) of the oesophageal margin (n = *10, 2·4 per cent) were diagnosed less often than early carcinomas in other sites* (n = *177, 18·9 per cent). Whereas 51·4 per cent of all resected carcinomas of the stomach showed no lymph node metastases (pN0), only 14·1 per cent of cardia carcinomas belonged to this category. With respect to operative treatment, Laurén's classification which defines the required margin of clearance according to diffuse type (frequency in cardia carcinoma 43 per cent, in other stomach sites 51 per cent), is of great significance. We believe that extensive oesophageal resection is necessary for patients with such difficult tumours. The pattern of metastasis in cardia carcinoma is similar to that of cancer in other stomach sites, the preferred area is the regional lymph nodes on the lesser curve (83 per cent). Histological classification and metastasis pattern show that cardia carcinoma is a type of carcinoma of the stomach which must be treated according to the criteria of stomach cancer surgery.*

Keywords: Carcinoma, stomach, cardia, surgery

The name 'cardia' to denote the 'mouth of the stomach' has been attributed to Galen, and malignant tumours of this region are known as cardia carcinomas. The definition is, however, not unequivocal. Operative tactics force surgeons to deal with this tumour as if it were an oesophageal tumour[1,2], whereas from an oncological point of view it can be classified as a stomach carcinoma[3–8]. Using epidemiological and histopathological data collected at the Department of Surgery of the University of Erlangen, we sought to clarify this problem.

Patients and methods

In the present study, a malignant lesion at the oesophageal–gastric margin is classified as a cardia carcinoma when this is a carcinoma of the fundus of the stomach which has reached the cardia or has crossed over to the distal oesophagus[9–11]. By definition the following tumours are not included: carcinoma confined to the fundus of the stomach, extensive carcinoma of the proximal third of the stomach with infiltration of several sections of the stomach, carcinoma in a Barrett's oesophagus[8,12,13] and squamous cell carcinoma of the distal oesophagus.

Adenocarcinoma in a Barrett's oesophagus and squamous cell carcinoma are carcinomas of the oesophagus.

All patients who underwent resection of cardia carcinoma between 1 January 1969 and 31 December 1985 were included in the analysis. Patients with carcinoma of the stomach in other sites during the same period served as controls. Clinical and histopathological data were prospectively recorded. Data from 422 patients with a cardia carcinoma and 937 patients with carcinoma of the stomach in other sites were analysed.

The histopathological assessment of the specimens (fixed in formalin), was done using the following classifications: pTNM, Borrmann's classification[14], histological classification using Laurén's method[15] and the 1977 UICC pathological staging. Laurén's classification was made according to the predominant type. All lymph nodes present in the fixed specimens were classified according to topography and were microscopically examined for malignancy at intervals of 300 μm.

When necessary, statistical significance was determined using a χ^2 test or trend test.

Results

Epidemiological data

The overall rate of cardia carcinoma, compared with that of all carcinomas of the stomach was 31 per cent (422 of 1359). In the first 15 years of the study period, we observed a shift in the pattern of stomach carcinoma towards the cardia (*Table 1*). In 1970, the ratio of cardia carcinoma to stomach carcinoma in other sites was 1:5·6, and by 1980 there was an increase in cardia carcinomas which changed the proportion to 1:1·7. The increase was observed in both sexes.

When one analyses the frequency of male and female patients with respect to tumour localization, one finds differing trends (*Table 2*). The predominance of male patients remains but although the number of female patients remained the same, the male:female ratio of cardia carcinomas increased from 0·27 to 0·53 in the period 1972–85. Because of the small number of patients who underwent resections for cardia carcinoma during the period 1969–71, a male to female comparison was not possible.

Histological classification

Histological classification of the tumours according to the World Health Organization classification showed no fundamental differences between the two sites (*Table 3*). The difference in the frequency of signet-ring cell carcinoma at the cardia (6·4 per cent) and at other sites in the stomach (12·5 per cent) was significant. This observation can be explained by Laurén's classification (*Table 4*): while the frequency of intestinal and diffuse type is nearly the same in carcinoma of the stomach in other sites, the intestinal type is the predominant type at the cardia. When analysing trends over time, we found that the frequency of the diffuse type of cancer at the cardia increased from around 30 per cent to about 50 per cent, while the rate of the diffuse type of carcinoma at other sites in the stomach remained relatively constant during the entire observation period.

The classification of the tumours according to their macroscopic appearance (Borrmann's classification) showed no differences between cardia and other stomach carcinoma (*Table 5*). As Bormann's classification shows, and this is confirmed by the pTNM classification (*Table 6*), cardia carcinomas are more likely to be found at an advanced stage than stomach carcinomas at other sites. Early cardia carcinomas are rare (2·4 per cent) compared with early carcinomas in other areas of the stomach (19·1 per cent). Most cardia tumours were classified in stages pT3 and pT4. Only 14·1 per cent of all resected specimens had no metastases in regional lymph nodes (pN0), compared with 51·4 per cent in other stomach carcinomas. Correspondingly, 86 per cent of all cardia carcinoma resections belonged to stages III and IV, whereas this was the case in only 55 per cent of carcinomas elsewhere in the stomach.

Dissemination of cardia carcinoma

Regional lymph node metastases from cancers of the cardia are found in the same sites as in other stomach carcinomas. The

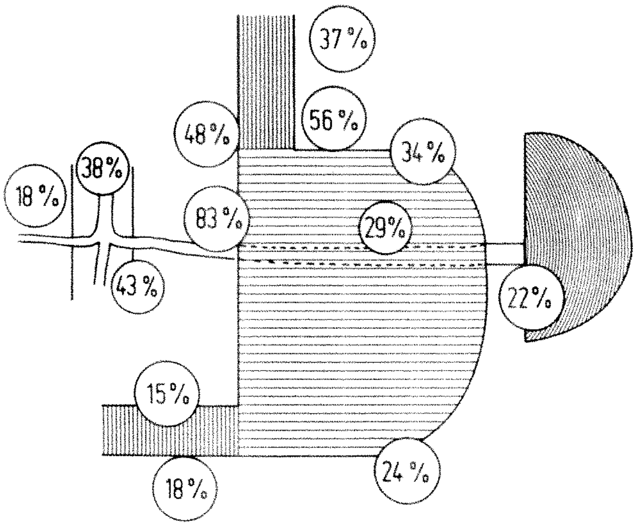

Figure 1 *Pattern of lymph node metastasis in 422 patients with cardia cancer*

main drainage takes place over the lesser curvature to nodes along the left gastric artery (83 per cent tumour involvement) to nodes around the coeliac artery (38 per cent tumour involvement). In about one-third of all patients in the present study of cardia carcinomas we found lymph node metastases along the greater curvature as well as along the splenic artery (*Figure 1*). In contrast to stomach carcinoma of the proximal third, in cardia carcinoma the paracardial and paraoesophageal lymph nodes were frequently tumour-infiltrated (48 and 37 per cent respectively). This mediastinal infiltration was of particular significance in planning resection.

Discussion

In the past three decades, the face of stomach carcinoma has changed. Three aspects are particularly striking: 1) the global frequency of carcinoma of the stomach has decreased or remained the same[16-19], while the frequency of tumours at other sites has increased; (2) parallel to this, there is a pylorocardial shift in tumour location[2,4,5,20,21]; and (3) at the same time, the predominance of male patients has diminished.

In our own patients we observed not only a relative increase but an absolute increase from 7 to 40 cases per year in the number of cardia carcinomas diagnosed during the observation period. The total number of resected stomach carcinomas at other sites remained constant at about 60 per cent. The data of Paterson *et al.*[17] in London must be similarly interpreted. The total number of cases during the observation periods 1951–55 and 1981–85 remained the same ($n = 96$ and $n = 94$), but the frequency of tumours in the proximal third of the stomach increased from 17 to 37, while the number of tumours in the middle and lower third of the stomach declined from 79 to 57. Such shifts must, however, be seen in a critical light when the series of patients is not homogeneous and patients are drawn from a large area. Further bias may result from the changing catchment areas of individual clinics and a changing specialization of different surgeons.

The increasing significance of cardia carcinoma is beyond doubt. We increasingly face the decisive question: in performing surgical therapy, should we follow the principles governing oesophageal surgery[1,2,20] or those governing the surgery of carcinoma of the stomach[4-7,15,21,22]?

The answer is extraordinarily difficult, in so far as cardia carcinoma has not been uniformly defined[10,11,23] nor are the described operative techniques identical. The classification into three types by Siewert *et al.*[11] is of theoretical interest. However, with respect to operative therapy, type I should be included among the malignant tumours of the oesophagus. Separating type II and type III can be difficult, but is easy in many tumours. This separation is of minor importance because the treatment for types II and III (Siewert's classification) is, with some limitations, identical to that used for Laurén's histological classification. Taking the classification used in the present paper as a basis, and on the strength of the histological results and pattern of metastasis, we regard cardia carcinoma as more akin to a carcinoma of the stomach which should be treated according to the principles of stomach cancer surgery.

The most important argument against this proposal is the high rate of local recurrences in the area of the oesophagojejunostomy as well as the relatively high rate of infiltration of mediastinal lymph nodes. The need for extensive oesophageal resection is based on these findings, and cardia carcinoma is consequently classified by some as an oesophageal carcinoma[1,2,20]. This results in a tendency to favour conservative techniques such as forms of endoscopic tumour management[24]. In our opinion, this is not justified.

As is the case of other stomach carcinomas, the histological type[3,5,15] should be considered in order to minimize local recurrences when undertaking surgery for cardia carcinoma[13]. Laurén's diffuse type is characterized by discontinuous growth, the appearance of which can mimic that of multiple tumours. A larger margin of clearance is therefore required for this tumour type (10 cm *in situ*) than for the intestinal cell type (4 cm *in situ*). If we consider these required margins of clearance, the apparent discrepancy in our views on cardia carcinoma disappears. A short distal oesophageal resection is sufficient for the intestinal type. In contrast, an extensive oesophageal resection with a high intrathoracic or cervical anastomosis is necessary to cure the diffuse type. If we take into account the frequency of both types, then classifying cardia carcinoma as an oesophageal carcinoma implies over-treatment for more than one-half of patients. Although extensive oesophageal resection is adequate in patients with the diffuse type, because we are dealing with a stomach cancer, substituting the oesophagus by an extended pedicled stomach is inadequate from an oncological point of view. We consider that this tumour type requires extensive oesophageal resection with total gastrectomy.

Hence, cardia carcinoma is an exception among the malignant tumours of the stomach as, in order to achieve a cure, the criteria which apply to treatment of stomach as well as to oesophageal carcinoma need to be taken into account. Cardia carcinoma should be considered a separate entity in order to obtain the best results for the patient. Finally, the use of Laurén's histological classification is essential if we are to avoid over-treatment as well as avoid a margin of clearance that is too narrow.

Announcement

Association of Surgeons in Training

Membership of the Association is open to all senior registrars holding accredited posts in general surgery, urology, plastic surgery, neurosurgery, orthopaedics, cardiothoracic surgery and paediatric surgery. Registrars in the above specialties who are 2 years post-fellowship may also apply. The Association represents the views of members on all matters relevant to surgical training besides holding scientific and social meetings. If you are not a member please contact the Secretary, Andrew McIrvine, 35, Elsie Road, Dulwich, London SE22 8DX, for details of membership, local representatives and forthcoming meetings. The next AGM will be held in Cardiff from 21–23 September 1989.

The dumping syndrome, which may follow partial gastrectomy or truncal vagotomy and drainage, may be refractory to treatment. The aim of this study was to determine the effect of the somatostatin analogue, SMS 201-995 (octreotide), on dumping provoked by hypertonic glucose. Ten patients with symptoms and signs of dumping were studied. After a dumping provocation test with placebo, all patients developed severe symptoms: seven patients had early dumping, two had both early and late dumping and one had late dumping alone. With either 50 or 100 μg SMS 201-995, the symptoms of early dumping were much reduced in all patients, and those of late dumping were completely abolished. The packed cell volume, pulse and systolic blood pressure changes of early dumping were significantly reduced by SMS 201-995 and the fall in blood glucose in patients with late dumping was abolished. SMS 201-995 may be a useful treatment for early and late dumping.

Keywords: Dumping, gastrectomy, vagotomy and drainage, somatostatin analogue SMS 201-995

The dumping syndrome, first described by Mix in 1922[1], is a symptom complex consisting of light-headedness, dizziness, fainting, nausea, abdominal distension and discomfort, with or without diarrhoea, which follows various forms of gastric surgery, particularly truncal vagotomy and drainage and partial gastrectomy. These symptoms are typically provoked by eating and appear to be related to the destruction of some of the normal regulatory functions of the upper gastrointestinal tract: rapid gastric emptying[2] is certainly important, but the various effects of extragastric vagotomy may also play a part[3]. Dumping is usually divided into two conditions: early dumping, in which fluid is thought to pass from the circulation into the gastrointestinal tract, and late dumping, which is reactive hypoglycaemia. In practice it can be difficult to distinguish clinically between the two and, indeed, many patients suffer from both.

Significant dumping afflicts approximately 5–10 per cent of patients after truncal vagotomy and drainage[4–6] and a similar proportion after partial gastrectomy[4]. Although these troublesome symptoms can often be managed medically by alterations in the diet and way of life or, as in Mix's original paper, surgically[1], a few patients remain refractory to treatment. Most surgeons with an interest in gastroenterology have a number of such 'gastric cripples' attending their clinics and therefore an effective treatment for this condition would be invaluable.

It is known that the plasma concentrations of several gut regulatory peptides are elevated in patients with the dumping syndrome[7–10], although it is not known whether this is a primary or a secondary phenomenon. These findings have, however, stimulated some interest in the use of somatostatin in this syndrome. Somatostatin is a naturally occurring 14-amino-acid peptide hormone which is widely distributed in the gastrointestinal tract. It inhibits the secretion of most gut regulatory peptides, decreases intestinal motility and secretion and reduces the splanchnic blood flow[11]. Two clinical trials on patients with the dumping syndrome, using natural somatostatin, have yielded encouraging results[12,13]. However the clinical use of natural somatostatin is limited since plasma somatostatin is rapidly cleared by circulating peptidases and its half-life in plasma is less than 3 min[11].

SMS 201-995 (octreotide, Sandoz Products Ltd., UK) is a synthetic somatostatin analogue. This octapeptide[14] has been shown to have a plasma half-life of 90 min in healthy volunteers[15]. It has a prolonged duration of action because of its resistance to biodegradation[15] and its high affinity with somatostatin receptors[16]. Oral administration is possible[17] and an oral preparation is currently being formulated. Thus, SMS 201-995 might fulfil many of the requirements of a practical treatment for the dumping syndrome.

The aim of this study was to determine the effect of SMS 201-995 on early or late dumping provoked by a dumping provocation test.

Patients and methods

Ten patients, 7 men and 3 women, with a mean age of 54 years (range 28–75 years), were studied. All patients had undergone some form of gastric surgery in the past and some had undergone multiple operations. The operations that had been performed before the study were Pólya gastrectomy (three patients), antrectomy with Roux-en-Y reconstruction (three patients), antrectomy with jejunal interposition (one patient), truncal vagotomy and gastroenterostomy (one patient), truncal vagotomy and pyloroplasty (one patient); one patient had a selective vagotomy alone, the previously performed gastroenterostomy having been taken down. In three patients (jejunal interposition, Roux-en-Y reconstruction and taking down of gastroenterostomy) the last operation had been performed for symptoms which included dumping. At the time of the study all ten patients had intractable symptoms of dumping which had proved refractory both to dietary manipulations and, in three patients, to revisional surgery.

After an overnight fast, a dumping provocation test was performed on each patient on three occasions using 350 ml 25 per cent glucose solution by the method previously described[18]. Two 5 ml samples of venous blood, 15 min apart, were taken before the test to establish the basal levels of the packed cell volume (PCV) and blood glucose. Samples were taken 10, 20, 30, 45, 60, 90 and 120 min after ingestion of hypertonic glucose for the same estimations. Samples were taken without the use of a tourniquet. The PCV was determined by the use of standard haematological techniques (Coulter counter, Coulter Electronics, Luton, UK) and the blood glucose by the glucose oxidase method.

Sixty minutes before the tests the patient received either a placebo or a subcutaneous injection of 50 or 100 μg SMS 201-995. The pretreatment was given in random order on separate days, so that after the three test days the patient had recevied each of the pretreatments. On each occasion the patient's symptoms, pulse and blood pressure were recorded at the above time points by an observer who was unaware of the treatment given. Unfortunately, owing to failure of venous access, the PCV data were not recorded on one patient after the 50 μg dose of SMS 201-995. In another patient the recording of the PCV, pulse and blood pressure was abandoned after a similar problem following the administration of 100 μg SMS 201-995.

Table 1 *The symptoms experienced during a dumping provocation test after a placebo and after 50 and 100 μg SMS 201-995 in the ten patients studied*

Patient	After placebo	After 50 μg SMS 201-995	After 100 μg SMS 201-995
1	Dizziness Nausea Diarrhoea	Nil	Nil
2	Fainting Nausea Severe diarrhoea	Mild discomfort Mild diarrhoea	Mild discomfort Mild diarrhoea
3	Dizziness Discomfort Diarrhoea	Nil	Nil
4	Fainting Diarrhoea	Nil	Nil
5	Nausea Dizziness Discomfort	Vague dizziness	Fatigue
6	Sweating Drowsiness	Mild drowsiness	Mild drowsiness
7	Discomfort Dizziness Diarrhoea	Nausea	Nausea
8	Dizziness Headache Discomfort	Nil	Nil
9	Nausea Abdominal pain Diarrhoea	Cold	Cold
10	Fainting Abdominal pain Diarrhoea	Nil	Nil

Statistical analysis was carried out using the Wilcoxon signed rank test.

Informed consent was obtained in all patients before performance of these studies.

Results

When the dumping provocation test was carried out with placebo, all patients experienced severe symptoms. The three most troublesome symptoms described by the patients are shown in *Table 1*, in the order in which the patients reported having experienced them. On the basis of the symptoms and the changes in PCV and blood glucose during the test, it was determined that seven patients had early dumping alone, two had a combination of early and late dumping and one had late dumping alone.

The symptoms of dumping were markedly reduced by both 50 and 100 μg SMS 201-995 (*Table 1*), only one patient having significant residual symptoms. Even in this patient the symptoms were ameliorated. The PCV and blood glucose results from the dumping provocation tests are illustrated in two typical patients: one with early dumping alone (*Figure 1*) and one with late dumping alone (*Figure 2*). The marked increase in PCV, which is the feature of early dumping illustrated in *Figure 1*, was diminished with either dose of SMS 201-995. The glucose tolerance was also reduced in this patient. Symptoms were also completely abolished with both doses of SMS 201-995. In the patient with late dumping (*Figure 2*), no increase in PCV followed the test, but 90 min after ingesting hypertonic glucose, the patient became hypoglycaemic and experienced typical symptoms of late dumping. The hypoglycaemia was abolished by either dose of SMS 201-995, as were the symptoms.

Analysis was carried out on the changes in PCV, blood pressure and pulse in the patients with early dumping. For comparison, the largest increment from the baseline levels in the direction that is commonly observed in early dumping was used for statistical analysis. Thus, for the PCV and pulse rate the maximum rise over baseline was chosen, whereas for systolic blood pressure, the maximum fall was used. The results are shown in *Figures 3, 4* and *5* respectively.

The median rise in PCV in the patients with early dumping (*Figure 3*) was 4·5 per cent with placebo, 1·2 per cent after 50 μg

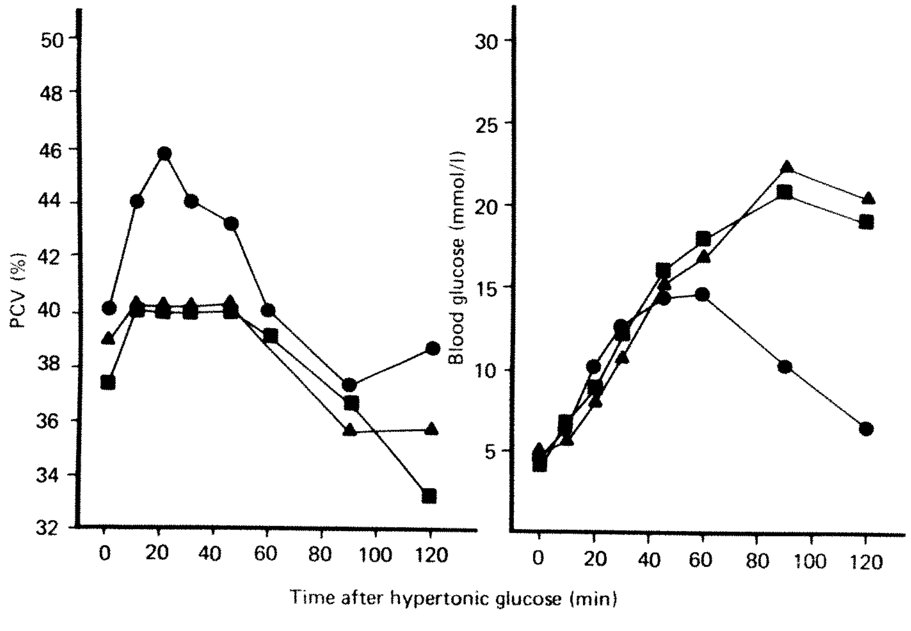

Figure 1 *The packed cell volume (PCV) and blood glucose response to a dumping provocation test in a patient with early dumping after placebo (●) and after treatment with 50 μg (■) and 100 μg (▲) SMS 201-995*

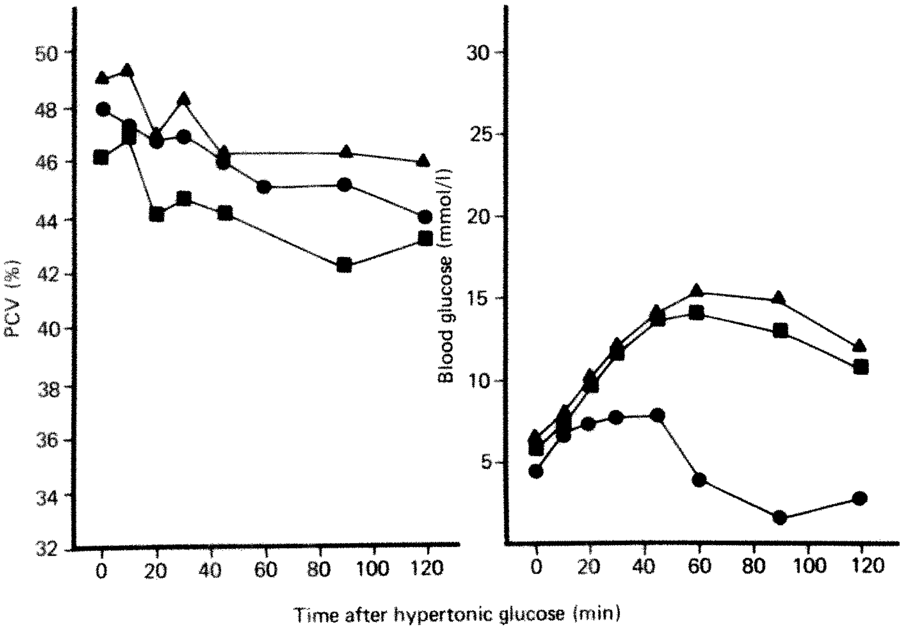

Figure 2 *The packed cell volume (PCV) and blood glucose response to a dumping provocation test in a patient with late dumping after placebo (●) and after treatment with 50 µg (■) and 100 µg (▲) SMS 201-995*

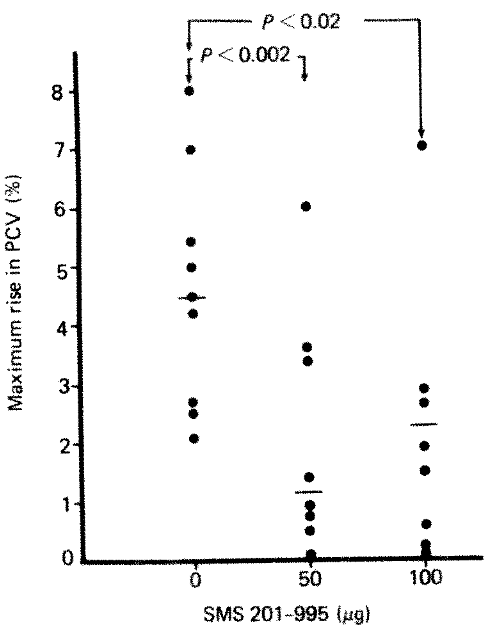

Figure 3 *The maximum rise in packed cell volume (PCV) in nine patients with early dumping after a dumping provocation test with placebo and after 50 µg and 100 µg SMS 201-995*

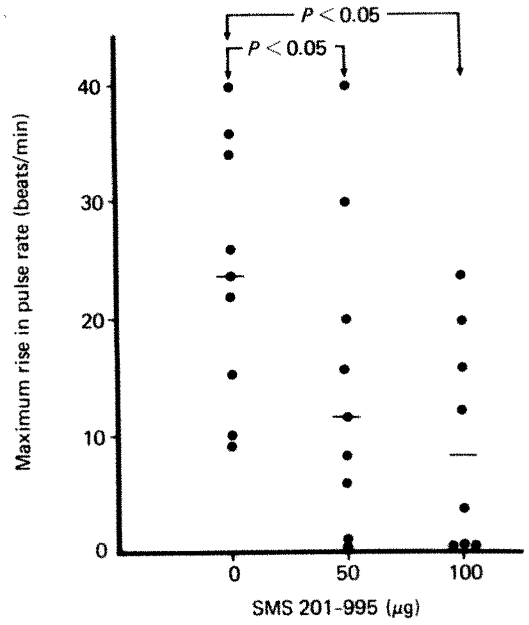

Figure 4 *The maximum rise in the pulse rate in nine patients with early dumping after a dumping provocation test with placebo and after 50 µg and 100 µg SMS 201-995*

SMS 201-995 ($P < 0.002$) and 2·1 per cent after 100 µg SMS 201-995 ($P < 0.02$). Similarly, the median rise in pulse rate (*Figure 4*) was 23 beats/min on placebo, 12 beats/min after 50 µg SMS 201-995 ($P < 0.05$) and 8 beats/min after 100 µg SMS 201-995 ($P < 0.05$). The fall in systolic blood pressure which was provoked when the placebo was given (*Figure 5*) was also significantly reduced by both doses of SMS 201-995 ($P < 0.05$). The fall in the blood glucose concentration which occurred in three patients with late dumping is shown in *Figure 6*. With either dose of SMS 201-995 the hypoglycaemia was abolished in each patient and symptoms of late dumping were absent.

Discussion

Dumping is a troublesome condition which is difficult to treat, and thus its occurrence is best prevented by avoiding truncal vagotomy and drainage or partial gastrectomy wherever possible. This is feasible in the surgical treatment of duodenal and gastric ulceration by the use of highly selective vagotomy, after which the incidence of dumping is very low[5]. However, there are occasions when this form of surgical treatment is inappropriate and because of this, and also because many patients have in the past been treated by means of these more destructive operations, an effective treatment for dumping would be of considerable importance.

We have demonstrated that SMS 201-995 is effective in the treatment of dumping provoked by hypertonic glucose. The symptoms of early dumping were virtually eliminated in nine of the ten patients and the accompanying changes in PCV, pulse and systolic blood pressure were also diminished. In three patients with late dumping the symptoms were completely abolished, as was hypoglycaemia.

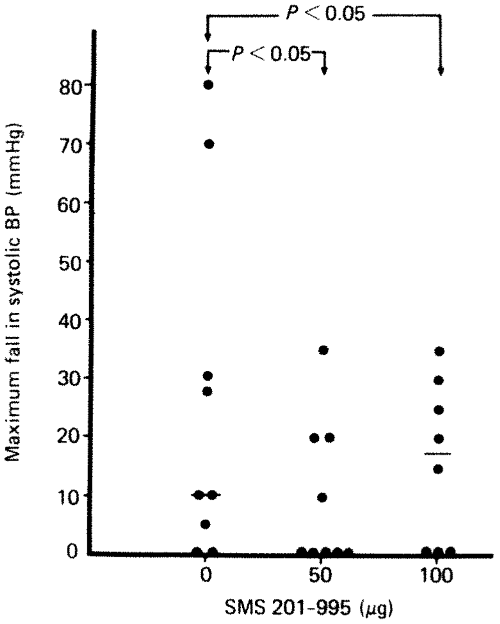

Figure 5 *The maximum fall in systolic blood pressure in nine patients with early dumping after a dumping provocation test with placebo and after 50 μg and 100 μg SMS 201-995*

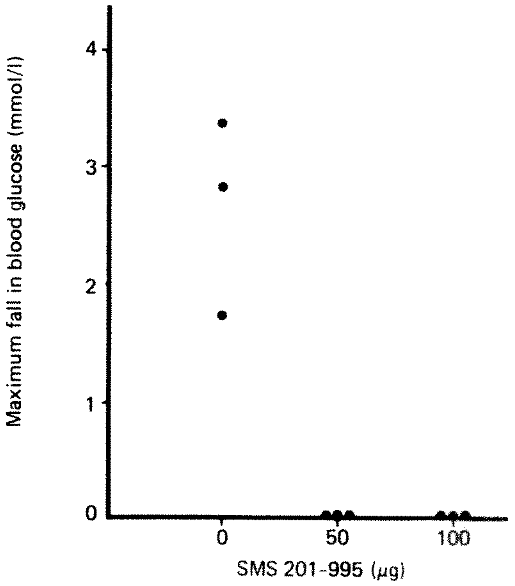

Figure 6 *The maximum fall in blood glucose in three patients with late dumping after a dumping provocation test with placebo and after 50 μg and 100 μg SMS 201-995*

These results are consistent with those of Long *et al.*[12], who studied the effect of natural somatostatin on dumping provoked by hypertonic glucose. They reported similar effects on the PCV and pulse rate with considerable symptomatic benefit to the patient. Reasbeck and Van Rij[13] reported similar results on PCV and pulse, also using natural somatostatin, but failed to demonstrate symptomatic benefit to the patient. This was because the symptoms of dumping were replaced by symptoms of abdominal colic. This effect was not seen in this study, using SMS 201-995.

The mechanism by which SMS 201-995 acts on dumping is not clear. In early dumping it may be that the slowing of gastric emptying which has been demonstrated in patients with dumping after treatment with SMS 201-995[19] may be important. Also, delayed intestinal transit and the reduction in gastrointestinal secretion, which is well documented with regard to somatostatin, may also be important[11]. Dumping is rare after highly selective vagotomy[5] but, when it occurs, is thought to be due to failure of receptive relaxation of the stomach. We have not had the opportunity to study such a patient after highly selective vagotomy and therefore do not know whether SMS 201-995 would be useful in these circumstances. The mechanism by which SMS 201-995 works in late dumping is easier to understand, as reactive hypoglycaemia, which is related to insulin secretion, may be diminished by SMS 201-995. It was noticeable in this study that the 100 μg dose produced no significant benefit over the 50 μg dose and it is possible that smaller doses of SMS 201-995 may be effective in dumping. In addition, the timing of the dose in our study (1 h before the test) means that the compound has a sufficiently long duration of action to be of practical use for a patient who complains of dumping.

The results of this preliminary study suggest that treatment with SMS 201-995 may be valuable in preventing dumping. However, whether the clinical benefit produced in the artificial circumstances of a dumping provocation test can be reproduced in more normal conditions, with the patient eating meals, remains to be seen. In addition, it may be that not all the symptoms associated with dumping may be similarly affected. The pathogenesis of diarrhoea, for instance, may be different from that of dumping[3] and diarrhoea may not respond to revisional surgery, even when this helps the other symptoms of dumping. In this study it was noticeable that diarrhoea was one of the symptoms which was not completely abolished by SMS 201-995, and the mild malabsorption which may occur with SMS 201-995[11] might even contribute to loose bowel actions.

Because the preparation is only available in a form suitable for parenteral administration, clinical trials will have to be confined to patients with the most severe, intractable symptoms. More widespread assessment should be possible when an oral formulation[17] becomes available, and this is expected soon. However, even if a beneficial effect can be demonstrated in patients suffering from dumping, the long-term nutritional and metabolic effects of SMS 201-995 will require careful study. This is particularly important because many patients who have had multiple gastric operations already have nutritional problems.

Acknowledgements

We thank Dr M. Dunne (Sandoz Products Ltd.) for the supplies of SMS 201-995.

A retrospective study of patients having gastroenterostomies was undertaken to identify predictive factors for the development of postoperative delayed return of gastric emptying (DRGE). A total of 322 consecutive patients underwent 324 gastroenterostomies; 35 experienced delayed return of gastric emptying. Regression analysis demonstrated preoperative obstruction to be the most significant factor ($P<0.001$)*. Vagotomy was not an independent variable. Age, sex, size of stoma, anastomotic technique, albumin and experience of the operator were not significant factors. Gastroenterostomy in the presence of 'gastric atony' was likely to produce DRGE. In all, 86 per cent of cases resolved spontaneously. Only one case of DRGE was found to have a mechanical cause. Most patients were supported by parenteral nutrition but, with a knowledge of the identified risk factors, more thought could be given to establishing a route for jejunal feeding at the time of surgery.*

Keywords: Gastroenterostomy, ulcer, vagotomy, pancreatic neoplasm

Delayed return of gastric emptying (DRGE) following gastroenterostomy is a problem known to most surgeons and has been referenced in the literature for over 50 years. Lewisohn[1] noted in 1936 that gastric atony was common in long-standing gastric outlet obstruction and could persist after gastroenterostomy. Jones and Eaton[2] postulated in 1933 that 'nutritional oedema' was the cause and suggested a preliminary feeding jejunostomy in the management of such patients.

Dragstedt and Woodward[3] found that vagotomy alone for uncomplicated duodenal ulcer sometimes resulted in DRGE: 15 of 234 patients in his original series required gastroenterostomy for relief of this problem. Subsequently, it has become routine to add a drainage procedure to a vagotomy. Vagotomy and drainage also came to be employed for patients with gastric outlet obstruction. Gastroenterostomy alone ceased to be a common procedure for ulcer disease. Although DRGE continued to be observed, the focus of attention was now on vagotomy as the cause. Experimental work by Nelson *et al.*[4] demonstrated the complexity of the effects of vagotomy on gastric motility. Weinstein *et al.*[5] reported a 17 per cent incidence of DRGE after vagotomy and gastroenterostomy for duodenal ulcer in a series of 73 patients. Although this series included 33 patients with preoperative gastric outlet obstruction, no indication was given that this increased the likelihood of DRGE.

Others[6–9], however, reported that preoperative obstruction increased the incidence of the problem significantly. This led to the conclusion that antecedent gastric outlet obstruction represented a contraindication to vagotomy and gastroenterostomy and that partial gastrectomy was preferable[5,6,7,9–11]. This view has not been universally accepted, given the additional mortality from gastric resection and the knowledge that DRGE will almost always resolve with time[7,9,12].

The aim of this study was to define the incidence of DRGE after gastroenterostomy performed for a variety of conditions. It was hoped thereby to identify patient groups most at risk of developing this complication with a view to minimizing the attendant morbidity.

Patients and methods

The records of all patients recorded as having a gastroenterostomy performed at Aberdeen Royal Infirmary in the 10 years from 1977 to 1986 were examined. The indication for operation, preoperative investigations, operative findings, operative procedure and postoperative course were recorded. A total of 344 patients were identified; four case histories were unobtainable and in 18 documentation was incomplete. This left 322 patients who had 324 gastroenterostomies. There were 196 men and 126 women (M:F ratio, 3:2). Ages ranged from 17–90 years (mean 59 years). Indications for operation were as follows: duodenal ulcer (233), carcinoma of pancreas (40), carcinoma of stomach (30), duodenal and periduodenal malignancy (9); and DRGE after previous surgery (12).

Definitions

The following definitions were used.

Gastric outlet obstruction. This was said to be present preoperatively when the symptoms and signs were suggestive and barium meal, endoscopy, operative findings or a combination of these also supported the diagnosis.

Prophylactic gastroenterostomy. This was performed where no evidence of obstruction existed.

Time at which gastric emptying was established. This was defined as the first day when all of the following criteria were met: patient tolerated oral fluids, no nasogastric tube *in situ*, intravenous fluid therapy discontinued; and no vomiting.

Delayed return of gastric emptying. This was defined as failure to establish gastric emptying by day 8 (see Discussion).

Exclusions

Patients who had previous or concurrent gastric resections were excluded as were those who had operations for morbid obesity.

Analytical method

The following factors were analysed to determine whether they were significant predictors of DRGE: preoperative obstruction, malignancy *versus* benign disease, vagotomy, age, site of gastroenterostomy, technique of gastroenterostomy, and preoperative albumin level.

Analysis was performed using the multiple regression programme in Statworks® (Cricket Software, Philadelphia, Pennsylvania, USA) run on an Apple® (Macintosh, Cupertino, California, USA) personal computer. The effect of gastric atony was analysed using χ^2 with Yates' correction.

Results

Eighteen patients (5·6 per cent) died within 30 days of operation. Nine patients died within 8 days without establishing gastric emptying; these patients are therefore excluded from further analysis. Six patients established gastric emptying but died within 30 days and are therefore included in subsequent analysis. Three patients died between day 8 and day 30 without establishing gastric emptying. These patients are therefore included in subsequent analysis. Two patients died after 30 days, without having established gastric emptying. These are included in subsequent analysis, but excluded from the above mortality figure.

The deaths were distributed as follows: carcinoma of pancreas (nine), carcinoma of stomach (four), bleeding duodenal ulcer (two), obstructed duodenal ulcer (two), perforated duodenal ulcer (one).

No patient was found, clinically, radiologically or at post mortem, to have an anastomotic leak.

Six patients had another operation before gastric emptying was established: one for bleeding on day 9; one for small bowel obstruction on day 10; four for DRGE on days 10, 17, 19, and 154. The patient with the small bowel obstruction was the only case found to have the mechanical cause for DRGE. These six patients are included in subsequent analysis.

In 76 per cent of cases the site of the stoma was described as posterior, in 12 per cent as anterior and in 12 per cent the site was not stated. All but two gastroenterostomies were performed with a two-layer hand sewn technique. A total of 304 patients with 304 gastroenterostomies established gastric emptying. Gastric emptying was established between day 1 and day 63 (mean, 5·4 days). All patients are considered together in *Table 1*.

All operations except those on patients dying within 8 days without having established gastric emptying, were then sorted into groups on the basis of the indication for operation, and further subdivided into those with preoperative obstruction (*Table 2*) and those without (*Table 3*).

Table 1 *Percentage of patients who established gastric emptying each postoperative week*

Postoperative week when fluids first tolerated	1	2	3	4	5+
Number of patients	270	22	2	7	3
Percentage of total	89	7	1	2	1

Another group of 12 operations could not readily be assigned to either of these categories as some degree of gastric atony was assumed to be present preoperatively. These patients could be considered as having DRGE or at least suboptimal gastric emptying as the indication for their gastroenterostomy. All 12 had previously undergone gastric surgery, eight within the previous month (four, vagotomy and pyloroplasty, one vagotomy and gastroenterostomy and three patching of perforated duodenal ulcer). All eight patients developed DRGE after the second operation.

A total of 37 gastroenterostomies in 35 patients was associated with DRGE; 22 out of 142 (15·5 per cent) were in the obstructed group, seven out of 161 (4·3 per cent) occurred in the non-obstructed group; eight out of 12 (67 per cent) occurred in the gastric atony group.

Of the 37 cases of DRGE 31 (84 per cent) were successfully treated conservatively. Reoperation was performed in six (see above).

Sixteen patients with DRGE were maintained on parenteral nutrition for a total of 28 patient days. One patient had a feeding jejunostomy at his third laparotomy. Four patients developed severe hypoalbuminaemia (serum albumin < 25 g/l). No patient had significant preoperative hypoalbuminaemia.

Analysis

Analysis of possible predictive factors revealed:

(1) preoperative obstruction increased the incidence of DRGE by a factor of 3·6:1 and this was significant ($t=3{\cdot}531$, $P<0{\cdot}001$)
(2) atony due to gastric surgery in the previous month resulted in DRGE in all eight cases compared with 9 per cent in the remainder of the patients combined ($\chi^2=52{\cdot}5$, $P<0{\cdot}001$)
(3) there was insufficient variation in anastomotic technique for meaningful analysis
(4) none of the patients had a low preoperative albumin, rendering analysis of this variable impossible
(5) none of the other factors analysed (vagotomy, age, malignancy, site of gastroenterostomy) achieved significance as an independent variable.

The results of the regression analysis are summarized in *Table 4*.

Table 2 *Incidence of delayed return of gastric emptying in subgroups of patients presenting with preoperative gastric outlet obstruction*

Indication	No. of patients	First day of function Mean	Median	Mode	No. of patients with delay	Delay (%)
Obstructed ulcer	77	5·1	3	4	8	10
Obstructed carcinoma of the stomach	28	4·8	4	3	3	10
Malignant obstruction of the duodenum	9	9·9	6	—	2	22
Obstructed carcinoma of the pancreas	20	8·4	6	—	5	25
Perforated obstructed ulcer	8	14·7	—	—	4	50
Total	142	6·3	4	4	22	15·5

Table 3 *Incidence of delayed return of gastric emptying in subgroups of patients presenting without preoperative gastric outlet obstruction*

Indication	No. of patients	First day of function Mean	Median	Mode	No. of patients with delay	Delay (%)
Perforated ulcer	40	4·3	4	4	0	0
Uncomplicated ulcer	98	4	3	3	4	4
Prophylactic (carcinoma of the pancreas)	16	5·7	6	6	2	12·5
Bleeding ulcer	7	6·7	3	3	1	14·3
Total	161	4·5	4	3	7	4·3

Table 4 *Summary of regression analysis of possible predictors of delayed return of gastric emptying*

Variable name	Coefficient	Standard error estimate	*t* statistic	Probability > *t*
Obstruction	0·126	0·036	3·531	0·000
Vagotomy	0·046	0·074	0·623	0·534
Posterior stoma	−0·044	0·058	−0·756	0·450
Malignancy	0·068	0·075	0·912	0·362
Age	0·000	0·001	0·350	0·727

Discussion

We have chosen in this paper to discuss the time at which gastric emptying was established. One cannot imply that this necessarily coincides with functioning of the gastroenterostomy. Where preoperative obstruction existed, this could be inferred, but it may be in the 'prophylactic' group that emptying recommenced via the pylorus in some patients. None the less, this made no practical difference to the identification of predictors of DRGE, or to the management of these patients.

The published incidence of DRGE after gastroenterostomy varies considerably, with rates from 0·5 to 27 per cent reported[5,7,9,13-15]. Most series have concentrated on duodenal ulcer surgery[5,7-9,13], but the problem has also been noted in patients with carcinoma of the pancreas[14,15]. Less seems to be known about the incidence when the gastroenterostomy has been performed for other indications. Some of the variation may be due to different criteria for defining 'delay'; 8[16], 10[7,9] and 14[8] days have all been used. A mathematical model based on the mean plus three standard deviations has been employed[9]. This does not seem appropriate in the heterogeneous group such as our series in which a normal distribution could not be anticipated. We chose 8 days as this was the time that most clinicians began to investigate the problem and initiate nutritional support. It is perhaps somewhat arbitrary, but there would have been little difference in our figures had we chosen 10 days. The overall number of DRGE cases would have been reduced by five. Repeating the regression analysis using 10 days produced a similar level of significance ($P<0{\cdot}001$).

Our results demonstrate that the only significant predictors are obstruction, or gastric atony following recent surgery. Although old age, malignancy and anterior stomas were all associated with an increase in the incidence of DRGE, analysis revealed that they were not significant independent variables. The possibility of a type 2 error should not be discounted, however. Malignancy, in particular, came close to achieving significance. There is a close correlation between increasing age and malignancy. When age is removed from the regression equation, malignancy achieves significance. We suspect that larger numbers would confirm this to be an independent variable. Vagotomy was associated with a lower incidence, but again was not a significant independent variable. It seems, therefore, that vagotomy *per se* cannot be blamed for this phenomenon in the majority of cases. Terms such as 'post-vagotomy gastric atony' may be misleading.

Hypoalbuminaemia has long been implicated as an aetiological factor. Although four patients developed severe postoperative hypoalbuminaemia, none had evidence of this preoperatively and it is therefore of no use as a predictor. None the less it is possible that in centres where patients present later with advanced malnutrition, this may be an important factor.

No consistent plan for management emerged from this study. Patients invariably underwent contrast examinations which were reported as demonstrating stomal oedema, gastric atony or no abnormality. There were no perceptible differences in the radiographic findings between those patients chosen for reoperation and those treated conservatively. A total of 84 per cent of patients responded successfully to conservative treatment and it seems likely that this figure could have been higher had more patience been forthcoming with four of the remaining patients. Given the likelihood of spontaneous resolution and the disappointing results of early reoperation, there seems to be little indication for early intervention in the majority. A contrast study can still be justified, however, as it may exclude a mechanical problem such as small bowel obstruction or intussusception of the stoma.

Metoclopramide was tried on some patients, but in such a haphazard manner that no conclusions could be drawn regarding its efficacy. McLelland and Horton[16] reported a 100 per cent success rate in a group of patients with DRGE after vagotomy and pyloroplasty. In contrast, Sheiner and Catchpole[17] reported no success at all with metoclopramide alone, but encouraging results with the addition of bethanechol in a small group of patients.

The main task of the clinician in managing this problem is providing adequate nutrition. Here this was achieved with parenteral nutrition, but this has actually been shown to reduce gastric emptying[18]. Furthermore it is expensive and entails the risks of central venous cannulation.

Since 1902[19] jejunostomy has been advocated as an adjunct to gastric surgery. It has been recommended specifically for non-functioning gastroenterostomy[20]. With the availability of fine-bore nasoenteric tubes and needle jejunostomy kits, it is worthwhile considering the prophylactic establishment of a jejunal feeding route in high-risk patients. If this is not undertaken at the time of surgery, a tube can still be introduced endoscopically once DRGE has been diagnosed.

We have confirmed that gastroenterostomy is safe and that the problem of DRGE almost invariably resolves with time. Better awareness of the predisposing factors and the natural history of this condition should lead to improved management. We can see no justification for favouring gastrectomy for obstructed ulcers on the evidence presented here.

Intussusception presenting as ileal reservoir ischaemia following restorative proctocolectomy

W. A. Kmiot and M. R. B. Keighley

The General Hospital, Steelhouse Lane, Birmingham
B4 6NH, UK
Correspondence to: Mr W. A. Kmiot

Intussusception is a rare cause of intestinal obstruction in adults[1]; it can be treated in the early stages by hydrostatic reduction[2]. We report the first case of ileal afferent limb–ileal reservoir intussusception following restorative proctocolectomy.

Case report

A 21-year-old Greek man, with a 10-year history of ulcerative colitis, was referred for surgery. After total colectomy and rectal excision, an ileal J pouch was constructed and anastomosed to the dentate line using a circular stapling device. No covering ileostomy was used and no mesenteric vascular division was necessary to achieve a tension free ileoanal anastomosis. Histology of the resected specimen showed extensive colitis with no evidence of Crohn's disease or carcinoma. On the fourth postoperative day, the patient complained of sudden-onset, constant lower abdominal pain which, over the next 48 h, became increasingly severe. It was associated with a tachycardia of 140 beats/min, a temperature of 39·5°C and lower abdominal tenderness. A contrast enema showed the staple lines to be intact, but the afferent ileal limb looked rigid with an effaced mucosa. The actual pouch contained filling defects suggestive of intussusception (*Figure 1*). At laparotomy, the pouch was oedematous and mottled from ischaemia, but was not gangrenous. An end ileostomy was constructed and the pouch excised.

Histology showed the distal pouch close to the initial anastomotic staple line to be microscopically normal. The afferent ileal limb showed localized haemorrhagic infarction with ischaemic necrosis extending to the upper, adjacent area of the pouch. There was submucosal venous thrombosis in the upper pouch but the major mesenteric arteries and veins were normal. Postoperative progress was stormy initially with the patient requiring intensive care, circulatory support and parenteral nutrition. Subsequently he made an uneventful recovery.

Discussion

The most common complications following restorative proctocolectomy and ileal reservoir formation are small bowel obstruction and pelvic sepsis occurring in 10–20 per cent and 5–20 per cent respectively[3,4]. In these cases surgical intervention is required in 20–40 per cent. Pouch ischaemia in many cases is encountered at operation and various vascular manoeuvres have been described to enable the ileal reservoir to be brought down to the dentate line without traction on the mesentery or undue tension on the pouch–ileal anastomosis[5].

Only 20 per cent of adults with intussusception present in the classical manner with vomiting, episodic abdominal colic, palpable mass and the passage of blood per rectum[1]. Our patient developed the signs and symptoms of intestinal vascular occlusion rather than obstruction.

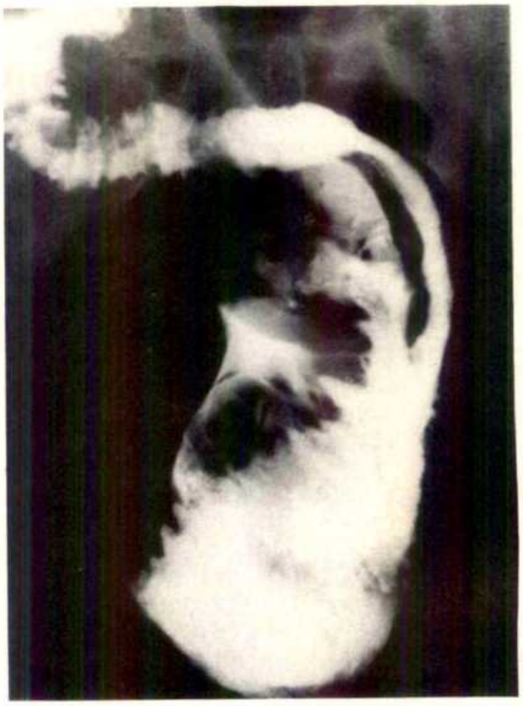

Figure 1 *Contrast enema pouchogram demonstrating filling defects suggestive of intussusception*

The contrast enema was in fact diagnostic, but hydrostatic reduction was unsuccessful. The histological findings of distal pouch viability and localized infarction suggest that afferent ileal limb resection may have been sufficient in this case.

We conclude that ileal afferent limb–ileal pouch intussusception is a cause of postoperative abdominal pain following ileal reservoir formation. Early suspicion will allow an attempt at non-operative hydrostastic reduction. A localized ileal resection may enable the reservoir to be preserved, but use of a proximal ileostomy will probably protect against this rare complication.

Branched chain amino acids as the protein component of parenteral nutrition in cancer cachexia

D. C. Hunter,
M. Weintraub,
G. L. Blackburn and
B. R. Bistrian

Laboratory of Nutrition and Infection at the Cancer Research Institute, New England Deaconess Hospital, Harvard Medical School, 194 Pilgrim Rd, Boston, Massachusetts 02215, USA

Correspondence to: Dr B. R Bistrian

A prospective randomized trial was conducted to determine the effects of branched chain amino acids (BCAA) as the protein component of total parenteral nutrition (TPN) on protein kinetics in patients with intra-abdominal adenocarcinoma. Nine malnourished patients were given both conventional TPN containing 19 per cent BCAA (AA) and isocaloric, isonitrogenous TPN containing 50 per cent BCAA (BCAA-TPN), in random order. Both [^{13}C]leucine and [^{14}C]tyrosine were employed as tracers to avoid the potential bias due to the different amino acid composition of the two TPN solutions. With BCAA-TPN, leucine and tyrosine flux increased significantly from (mean±s.d.) 158·0±37·2 to 243·5±75·8 $\mu mol\,kg^{-1}\,h^{-1}$ (P<0·025) and from 35·0±8·4 to 42·6±11·0 $\mu mol\,kg^{-1}h^{-1}$ (P<0·05) respectively. Leucine oxidation was significantly higher on BCAA-TPN (24·1±6·3 on AA versus 68·3±37·1 $\mu mol\ kg^{-1}h^{-1}$, P<0·025) while tyrosine oxidation was significantly lower (3·7±1·8 $\mu mol\,kg^{-1}\,h^{-1}$ on AA versus 2·5±2·0 $\mu mol\,kg^{-1}\,h^{-1}$ on BCAA-TPN, P<0·05). Whole body protein synthesis and breakdown was significantly higher on BCAA-TPN by the tyrosine tracer (31·3±7·3 on AA versus 40·1±9·3 $\mu mol\,kg^{-1}\,h^{-1}$, P<0·025 and 33·0±8·4 on AA versus 41·3±11·1 $\mu mol\,kg^{-1}\,h^{-1}$, P<0·05) respectively. Using the leucine tracers both synthesis and breakdown were increased, but not significantly, from 133·8±40·0 to 175·3±65·1 $\mu mol\,kg^{-1}\,h^{-1}$ and from 127·9±33·6 to 167·7±71·2 $\mu mol\,kg^{-1}\,h^{-1}$ respectively. The fractional albumin synthetic rate increased significantly on BCAA-TPN from 4·3±2·9 on AA to 8·0±5·1 per cent per day (P<0·05). The reduction in tyrosine oxidation, suggesting improved protein utilization, coupled with an increase in protein and albumin synthesis, strongly support a positive benefit from BCAA-TPN in cancer cachexia.

Keywords: Cancer cachexia, branched chain amino acids

The cause of cancer cachexia, the progressive weight loss of malignant disease, remains enigmatic. The anorexia of gastro-intestinal malignancy may be related to mechanical obstruction[1] or chronic pain[2], yet the resulting weight loss and biochemical abnormalities often cannot be explained by starvation alone. Weight loss and anorexia may precede other symptoms of malignant disease and not be obviously related to tumour size or the number of metastases[3]. Small lung tumours, unassociated with either pain or gastrointestinal disturbances, can present with profound weight loss. The associated metabolic changes also are not consistent with starvation alone, but are more akin to the metabolic response seen in response to injury[4,5]. The idea that the tumour itself may be responsible for the changes by some intermediary metabolite or hormone has prompted much research without positive identification of a putative agent.

It has been shown in both animals and humans that tumours can be responsible for an increase in whole body protein turnover, reduced protein synthesis in muscle, and an increase in liver protein synthesis[6]. When combined with hypoalbuminaemia and hypotransferrinaemia, these changes are reminiscent of the metabolic response to injury, although of a far lesser magnitude[4,5]. It has also been shown in large tumours that there is an increase in anaerobic metabolism with the production of lactate which is then utilized by the liver via the Cori cycle for gluconeogenesis[7,8]. This process is energetically inefficient and may contribute to the increase in metabolic rate and the disproportionate (over and above starvation alone) weight loss seen with malignant disease or following injury. Branched chain amino acids (BCAA) have been shown to be uniquely effective in reducing protein catabolism in both the injured animal and in humans[9–11]. Recent evidence also supports similar effects of BCAA in cancer-bearing animals and humans[12,13].

As BCAA occupy a unique position in the injury-type metabolism of malignant disease, it was decided to confirm the benefit of infusions of BCAA in a prospective randomized trial in which the patients, acting as their own controls, received both conventional total parenteral nutrition (TPN) and BCAA-enriched TPN (BCAA-TPN). To avoid the potential bias that might result when using an amino acid tracer that is also the major diet variable, both [^{14}C]tyrosine and [^{13}C]leucine were employed.

Patients and methods

Nine malnourished patients with intra-abdominal adenocarcinoma, proved by tissue histology, were chosen for this study.

Signed informed consent was obtained for the study including the use of a radioactive tracer, in full accordance with, and approval of, the Institutional Review Board and Radiation Safety Committee of the New England Deaconess Hospital

All patients underwent a full nutritional history and their height, weight and upper arm anthropometric measurements were made The initial nutritional assessment also recorded the total lymphocyte count and serum secretory protein concentrations, including albumin and transferrin. Patients were tested for delayed hypersensitivity with common recall antigens by the Multitest CMI (Merieux Institute, Miami, Florida, USA). In addition a number of nutritional indices were calculated, including· the basal energy expenditure using the Harris–

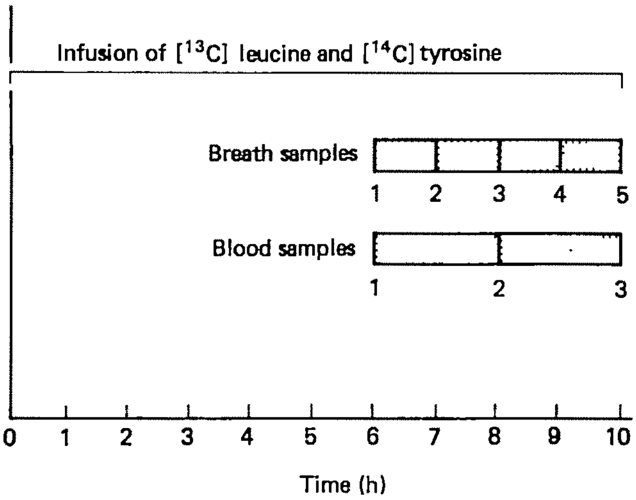

Figure 1 *Experimental design of the infusion study*

Benedict formula[14], hospital prognostic index[15]; catabolic index[16]; creatinine height index[17], and prognostic nutritional index[18].

A 24-h collection of urine for total nitrogen was obtained and the nitrogen balance calculated. (The difference between dietary nitrogen intake and urinary nitrogen excretion plus the faecal and unmeasured nitrogen loss was estimated at 4 g day^{-1})

Patients were studied while receiving a high BCAA formula containing 50 per cent BCAA, or regular TPN containing 19 per cent BCAA (AA) with the order being assigned randomly from a list generated by the pharmacy Patients were then crossed over and studied on the other TPN solution.

The stock solutions from which the TPN was made consisted of Travasol 10 per cent solution (Travenol Laboratories, Deerfield, Illinois, USA) containing 19 per cent BCAA, dextrose 70 per cent and 20 per cent lipid emulsion For the high BCAA solution, Branchamin (Travenol Laboratories) was added to the stock solution in a 4 per cent equimolar solution to bring the BCAA content up to 50 per cent.

The TPN was given as 1 2 g protein kg^{-1} bodyweight day^{-1} and energy as 1 3 × basal energy expenditure day^{-1}by a continuous infusion IMED pump (IMED, San Diego, California, USA) The two study solutions were matched for both nitrogen content and calories. All patients also received their necessary electrolytes, vitamins and minerals Patients received each of the TPN solutions for a minimum of 24 h

Procedure (Figure 1)

The protein turnover study lasted from midnight to 10 00 hours, 50 μCi [^{14}C]tyrosine and 400 mg [^{13}C]leucine having been aseptically added to the TPN solution at the beginning of the period.

During the study, patients were confined to bed and were limited to the consumption of clear fluids. At 06 00 hours and hourly until 10.00 hours, breath samples were collected and analysed for $^{14}CO_2$ and $^{13}CO_2$. At 06 00, 08.00 and 10.00 hours 20 ml whole blood was obtained in heparinized tubes for amino acid analysis. The plasma was separated and stored at −30°C until analysis Baseline enrichments had been obtained before starting the study

At 10.00 hours the flow rate of the IMED pump was measured and the exact volume that was infused was calculated At the same time the patient's oxygen consumption and carbon dioxide production were measured using the Beckman Metabolic Chart (Sensormedics, Anaheim, California, USA).

Analysis and calculations

Plasma amino acid concentrations were measured by ion-exchange chromatography using an amino acid auto-analyser (Dionex D-400, Sunnyvale, California, USA)

$^{14}CO_2$ specific activity was measured on a scintillation counter (Beckman, Fullerton, California, USA) after first trapping 1 mmol CO_2 in a solution of hyamine hydroxide, absolute alcohol and a commercial scintillant (Betafluor National Diagnostic, Somerville, New Jersey, USA) with phenolphthalein as an indicator

$^{13}CO_2$ enrichment was measured by a dual collector isotope ratio mass spectrometer (model 3-60 RMS, Nuclide Corp State College, Pennsylvania, USA).

Plasma [^{14}C]tyrosine specific activity was measured by the method of Garlick and Marshall[19].

[^{13}C]leucine enrichment was determined by isolation of the free amino acid and then derivitization to the N-acetyl, N-propyl ester which was then analysed on the Quadropole Mass Spectrometer (Hewlett-Packard 5985B, Palo Alto, California, USA).

Leucine and tyrosine kinetics, flux, breakdown and protein synthesis were calculated using the Waterlow stochastic model[20] The model explains the following relationship

$$Q=S+O=I+B$$

where Q = flux, S = protein synthesis, O = protein oxidation, I = leucine intake, and B = leucine released by protein breakdown These parameters are expressed as μmol kg^{-1} bodyweight h^{-1}.

Flux is calculated by the equation:

$$Q=\imath\left[\frac{E_\imath}{E_p}-1\right]$$

where $\imath$ is the infusion rate of [^{13}C]leucine, $E_\imath$ is the enrichment of [^{13}C]leucine infused (=atom per cent excess) and E_p is the plasma enrichment of [^{13}C]leucine at plateau. $^{13}CO_2$ (μmol kg^{-1} h^{-1}) production from [^{13}C]leucine oxidation is calculated by the equation

$$V_{^{13}CO_2}=\frac{V_{CO_2}\times E_{^{13}CO_2}}{\text{bodyweight}}\times\frac{60\times 44{\cdot}6}{100\times 0{\cdot}81}$$

where V_{CO_2} is the CO_2 production rate (ml min^{-1}), $E_{^{13}CO_2}$ is the $^{13}CO_2$ enrichment in expired air at isotopic steady state (atom per cent excess) and bodyweight is in kilograms. The constant 60 converts minutes to hours, 44 6 converts millilitres leucine to micromoles leucine (at standard temperature and pressure), 100 changes atom per cent excess to a fraction and 0·81 accounts for $^{13}CO_2$ released by [^{13}C]leucine oxidation but not released from the body bicarbonate pool into the expired air

Leucine oxidation is then calculated as

$$O=V_{CO_2}\left[\frac{1}{E_p}-\frac{1}{E_\imath}\right]\times 100$$

Thus, synthesis can be derived from $S=Q-O$ breakdown by the equation $B_{leu}=Q_{leu}-I_{leu}$ (where I = total leucine infused) and leucine balance = $S-B$.

The above equations are the same for tyrosine except that specific activity is substituted for atom per cent excess, and there is an additional factor in the appearance side of the equation $Q_{tyr}=S_{tyr}+O_{tyr}+N$ (where N = *de novo* synthesis of tyrosine) as tyrosine is a non-essential amino acid. Similarly, isotope balance is estimated as $S-B$, since S is overestimated by the equation $S=Q-O$. To account for this, tyrosine balance was also calculated using results from the leucine studies In this method if one assumes both tyrosine and leucine equilibrate in the same pool, and random breakdown of body protein, then tyrosine and leucine should appear in proportion to their concentration in total body protein (7 5 leucine 3 5 tyrosine)[21]. Thus, if one multiplies the leucine breakdown by 3 5/7·5 one should obtain the amount of tyrosine from protein breakdown (and thus not from synthesis from phenylalanine) (i.e. estimated breakdown of tyrosine = 3 5/7 5 × breakdown of leucine and an estimate for N (*de novo* synthesis): this would be $N=(Q_{tyr}-I_{tyr})-$ estimated B_{tyr})

The albumin was extracted from plasma by precipitation with 20 per cent trichloroacetic acid and then it was resolubilized in an ethanol/water solution. A portion of the extraction was counted while another portion was measured for albumin concentration using a dye-binding technique The specific activity was then calculated on the basis of d p.m. g^{-1} albumin. Statistical analysis included means, standard deviations, paired t tests and linear regression analyses. Protein kinetic data were evaluated using one-tail t tests on the basis that this was a confirmatory trial[13]. Standard two-tailed tests were employed for the plasma amino acid levels The level for significance was set at $P<0\ 05$.

Results

Nine patients, all of whom had demonstrated recent weight loss, completed the study. The mean (±s d.) age was 66·4±6·4 years, the mean weight was 53·8±9·7 kg and mean weight loss was 8 7 kg or 16 per cent of bodyweight. Five of nine patients had suffered a weight loss > 10 per cent of usual bodyweight. Only one patient had a serum albumin concentration >3 g dl^{-1} and the mean concentration was 2·6±0·4 g dl^{-1}. Two-thirds of the patients were anergic to common recall antigens (*Tables 1* and *2*).

The patients remained in a metabolically steady state throughout the study. Their resting energy expenditures, mean 1349 kcal day^{-1} on the BCAA-TPN solution and 1433 kcal

day^{-1} on AA, were not statistically different. Their respiratory quotients were 0·90 on BCAA-TPN and 0·92 on AA, demonstrating perhaps slight underfeeding but no significant differences between the diets.

Leucine data were not obtained for three of the patients. Leucine flux and oxidation increased significantly on BCAA-TPN, from 158·0±37·2 on AA to 243·5±75·8 μmol kg^{-1} h^{-1} on BCAA-TPN and from 24·1±6·3 on AA to 68·3±37·1 μmol kg^{-1} h^{-1} on BCAA-TPN respectively ($P<0·025$). Both synthesis and breakdown were increased on BCAA-TPN but not significantly. Synthesis increased from 133·8±40·0 on AA to 175·3±65·1 μmol kg^{-1} h^{-1} on BCAA-TPN and breakdown increased from 127·9±33·6 to 167·7±71·2 μmol kg^{-1} h^{-1}. Isotope balance (synthesis–breakdown) was not significantly different in the two solutions: 7·7±44·3 μmol kg^{-1} h^{-1} on BCAA-TPN and 5·9±8·8 μmol kg^{-1} h^{-1} on AA. The percentage of the flux oxidized was increased on BCAA-TPN but again failed to reach statistical significance (16·5±7·4 per cent on AA and 28·0±12·6 per cent on BCAA-TPN).

This situation was closely simulated using the tyrosine tracer. Tyrosine flux increased from 35·0±8·4 on AA to 42·6±11·0 μmol kg^{-1} h^{-1} on BCAA-TPN ($P<0·05$) and there was significant improvement in protein synthesis from 31·3±7·3 on AA to 40·1±9·3 μmol kg^{-1} h^{-1} on BCAA-TPN ($P<0·025$). Breakdown also increased significantly from 33·3±8·4 on AA to 41·3±11·1 μmol kg^{-1} h^{-1} on BCAA-TPN ($P<0·05$) but the increase in protein synthesis was not as great, so that isotope balance, reflecting protein balance, was improved although not to a level of statistical signficance (from −1·7±1·7 on AA to −1·2±2·1 μmol kg^{-1} h^{-1} on BCAA-TPN). Tyrosine oxidation decreased from 3·7±1·8 μmol kg^{-1} h^{-1} on AA to 2·5±2·0 μmol kg^{-1} h^{-1} on BCAA-TPN ($P<0·05$). The percentage of the flux oxidized was also decreased on BCAA-TPN from 10·6±4·7 per cent on AA to 5·4±2·9 per cent ($P<0·01$). There was a significant increase in albumin fractional synthetic rate from 4·3±2·9 on AA to 8·0±5·1 per cent per day ($P<0·05$) when receiving BCAA-TPN (see *Table 3* for summary).

The results of the patients' amino acid profiles (*Figure 2*) revealed that BCAA-TPN had no effect on the concentrations of taurine, aspartate, glutamine, glutamate and alanine. The levels of threonine (0·158±0·041 on AA and 0·094±0·024 μmol ml^{-1} on BCAA-TPN), serine (0·112±0·030 on AA and 0·087±0·019 μmol ml^{-1} on BCAA-TPN), glycine (0·432±0·102 on AA and 0·324±0·092 μmol ml^{-1} on BCAA-TPN) and methionine (0·062±0·027 on AA and 0·044±0·032 μmol ml^{-1} on BCAA-TPN) were all significantly reduced on BCAA-TPN

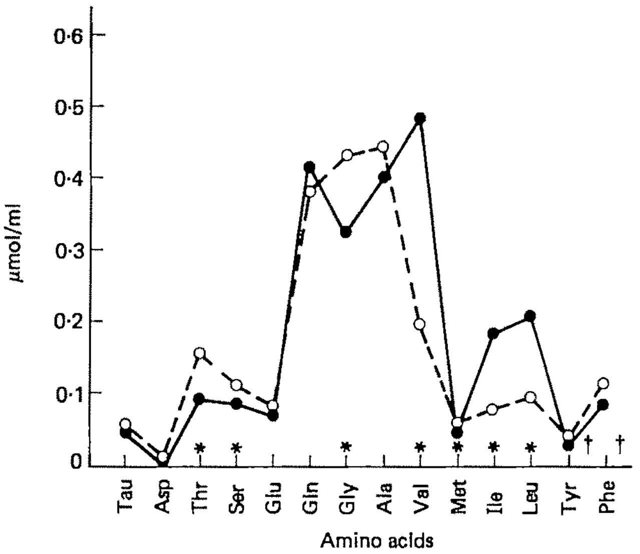

Figure 2 *Amino acid profile with the two infusions* ●, *50 per cent branched chain amino acids,* ○, *19 per cent branched chain amino acids,* *$P<0{\cdot}001$, †$P<0{\cdot}01$

($P<0{\cdot}001$) Phenylalanine (0·114±0·027 on AA and 0·085±0·014 μmol ml^{-1} on BCAA-TPN) and tyrosine levels (0·041±0·021 on AA and 0·028±0·015 μmol ml^{-1} on BCAA-TPN) were also significantly reduced on BCAA-TPN ($P<0{\cdot}01$). Serum concentrations of leucine (0·096±0·019 on AA and 0·208±0·047 μmol ml^{-1} on BCAA-TPN), isoleucine (0·077±0·019 on AA and 0·187±0·054 μmol ml^{-1} on BCAA-TPN) and valine (0·198±0·043 on AA and 0·485±0·136 μmol ml^{-1} on BCAA-TPN) were all significantly increased with the BCAA-TPN solution ($P<0{\cdot}001$). To discern whether these results could be explained in part by the nutritional status of the patients, regression analyses of the albumin synthetic rate to serum albumin, and tyrosine oxidation rate to weight loss were performed. There was no significant correlation between the patients' serum albumin and the fractional albumin synthetic rate ($r=0{\cdot}36$ for the AA infusion, $r=0{\cdot}18$ for the BCAA-TPN infusion). A strong, direct correlation between endogenous tyrosine oxidation rate and weight loss, however, was found with the BCAA-TPN infusion ($r=0{\cdot}79$) but not with AA infusion ($r=0{\cdot}01$). This suggests that those patients with greater weight loss were more catabolic. When taken in conjunction with the finding of a reduced tyrosine oxidation rate in the BCAA-TPN group, this suggests that the response to BCAA is related to nutritional status, with greater response in the better nourished

Discussion

It is well established that malnutrition from whatever cause leads to an increase in the morbidity and mortality rates from disease For this reason nutritional support has been used, particularly as an adjunct in the treatment of malignant disease. There is good evidence that preoperative TPN can improve perioperative morbidity and mortality rates in gastrointestinal cancer surgery and that this may in part be due to improved immunocompetence[22-24]. There is a debate however about whether conventional TPN reliably repletes body protein stores or improves long-term survival during oncological chemotherapy[23-25]. Owing to the unique metabolism of BCAA, it was felt that infusion of BCAA might act as a fuel source for the muscle and thereby limit net muscle protein breakdown in cancer cachexia Ultimately one might expect an improved clinical outcome of cancer chemotherapy if improved nutritional outcomes could be produced

A previous kinetic study with BCAA-TPN used [^{14}C]leucine as an isotope tracer[13]. This showed an increase in leucine flux, oxidation, synthesis, breakdown and balance as well as an increase in albumin synthetic rate. These were all significant except the leucine breakdown. Protein flux and oxidation would be expected to be increased by virtue of the increased dietary intake of leucine, but the changes in synthesis and balance were considered to be unbiased findings. However, there were concerns that the oxidation, although increased with BCAA-TPN, might be an underestimate due to oxidation occurring intracellularly rather than in the plasma where the flux measurements are made owing to the extracellular–intracellular gradient for leucine. Because of the concerns about whether distorted results might be obtained when greater quantities of leucine were found in one of the experimental diets, it was decided to confirm the results by employing [^{14}C]tyrosine as the primary tracer. [^{13}C]leucine was concomitantly infused, both to allow close comparison with previous studies and to estimate the *de novo* synthesis of tyrosine from phenylalanine. As the tracer [^{14}C]tyrosine is radioactive, it was not possible to use an additional radioactive isotope in humans. For this reason, [^{13}C]leucine, the naturally occurring stable isotope of leucine, was used. This may have some theoretical disadvantage, as in using this compound appreciable amounts exceeding 'tracer' quantities must be infused to obtain adequate samples for analysis

Using the tyrosine tracer, the flux was increased and oxidation decreased on BCAA-TPN. As neither solution (AA nor BCAA-TPN) contains significant amounts of tyrosine (1·8 per cent flux in BCAA-TPN and 3·8 per cent flux in AA), this presumably represents a true influence of the BCAA-TPN, the reduced oxidation reflecting an improvement in amino acid reutilization. The leucine tracer showed a significant increase in oxidation, but in this case it was felt to be due largely to the substantially increased concentration of leucine in the diet (32·4 per cent flux in BCAA-TPN and 19 per cent flux in AA) of the BCAA-TPN solution. Both tracers demonstrated an increase in flux with BCAA-TPN which must, by definition, be associated with an increase in breakdown and this was significant by the tyrosine tracer There is, however, a simultaneous increase in protein synthesis which can be attributed to the increased leucine concentration, perhaps reflecting leucine's role as a modulator of protein synthesis in muscle. An increase in the fractional albumin synthetic rate also strongly supports a positive benefit from BCAA-TPN.

In calculating the *de novo* synthesis of tyrosine from phenylalanine, using the leucine breakdown (×3·5/7·5) in the tyrosine equation, negative synthetic rates are obtained, which is clearly not possible In using this calculation it is assumed that both leucine and tyrosine remain in the same metabolic pool, are treated equally, and that the appearance of amino acids from protein breakdown are in exact proportion to their relative abundance in body protein. In this instance the amino acid distribution in the diet is distinctly different from the usual composition in body proteins. Since dietary intake makes such a large contribution to the whole body leucine flux, we might anticipate that there would not be a good correlation between the results determined by the two tracers. In fact, even though leucine and tyrosine tracers showed equivalent results, they did not correlate well and this must, at least in part, be due to the reason above None the less, in a qualitative sense, similar information would result whichever tracer was employed Thus leucine remains a useful tracer of protein kinetics in situations where the experimental diets are dissimilar in leucine content

The results of the amino acid profiles are of some interest. The reduced concentrations of phenylalanine, tyrosine, threonine, glycine, serine and methionine most likely reflect a lower concentration in the BCAA-TPN solution. The BCAA-TPN solution had no differential effect on taurine, aspartate, glutamate, glutamine and alanine Thus, despite the decrease in dietary intake, alanine levels were maintained by the BCAA-TPN solution Presumably this is due to the increased BCAA oxidation which would increase *de novo* alanine synthesis[26]. Glutamate and glutamine have been shown to be important factors in maintaining nitrogen balance[27] and glutamine plays an important role in the maintenance of the nutrition of the gastrointestinal trace, particularly enterocyte structure and function[28] The levels of both these amino acids were maintained on the BCAA-TPN solution even with the reduced intake. This is, once again, presumed to be due to increased *de novo* synthesis of glutamine with increased BCAA oxidation[26]. As expected the levels of leucine, isoleucine and valine were dramatically increased, confirming that the increased dietary intake leads to increased serum concentrations.

In summary, this study confirmed that an increase in BCAA in the diet leads to an increase in circulating plasma levels. These higher levels are the putative agent responsible for an increase in protein flux and breakdown, with a reduction in protein oxidation and an increase in protein synthesis and fractional albumin synthetic rate as determined by [^{14}C]tyrosine. These results confirm improved protein utilization with the BCAA-TPN solution as compared with the standard TPN solutions in cancer cachexia, with a suggestion that the response may be dependent on nutritional status. Whether these metabolic benefits of feeding a BCAA-enriched diet will translate into clinical benefit in cancer cachexia is unknown and uncertain. However, previous studies of parenteral feeding in cancer patients with standard formulae has been found to be less effective at protein repletion than in similarly malnourished patients without cancer[25]. Furthermore, parenteral feeding with standard formulae has not been shown to improve consistently clinical response or mortality in randomized trials employing TPN and chemotherapy[24]. BCAA-enriched TPN in cancer cachexia might be associated with benefits clinically, but randomized trials are necessary to explore these possibilities. With two positive studies of the value of BCAA in cancer cachexia in humans now available, perhaps the opportune time for such trials has arisen.

Isotopic studies during surgical convalescence

We have performed paired isotopic studies in four patients undergoing resection of early colorectal cancer and four having removal of parathyroid adenomas. Kinetic measurements of protein and glucose metabolism were made before resection and at home 10 weeks after surgery. During convalescence there were major changes in both groups in glucose metabolism and the hormonal milieu despite no alterations in protein kinetics or metabolic rate. In particular, the rate of glucose production doubled from (mean ± s.e.m.) 14·8 ± 1·3 to 28·1 ± 2·5 μmol kg^{-1} min^{-1} ($P < 0{\cdot}01$), the percentage of available glucose undergoing oxidation decreased from 35·5 ± 3·9 to 21·5 ± 2·9 per cent ($P < 0{\cdot}05$) *and the percentage of glucose undergoing recycling to lactate increased from 20·1 ± 10·0 to 52·9 ± 2·3 per cent* ($P < 0{\cdot}05$). *During convalescence the basal plasma insulin concentration was significantly higher* ($P < 0{\cdot}05$) *and there was a proportionately smaller response to glucose infusion. The convalescent state was also associated with an elevation in serum cortisol from 291 ± 54 to 496 ± 75 nmol litre*$^{-1}$ *(*$P < 0{\cdot}05$*). The values for resting energy expenditure were not significantly different from the predicted energy expenditure in either the preoperative or the convalescent groups. We conclude that (a) there is a marked increase in both glucose production and glucose recycling to lactate in convalescence from clean uncomplicated surgery, and this is associated with a decrease in the percentage of glucose uptake oxidised; (b) a relative hyperinsulinaemia is seen in convalescent patients and is associated with decreased responsiveness to a glucose load; (c) the plasma cortisol level is significantly elevated after 10 weeks of convalescence; and (d) convalescent patients do not have elevated rates of protein catabolism or energy expenditure.*

Keywords: Convalescence, isotopes, recycling

The metabolic and hormonal response to various forms of stress, including operative trauma, has been extensively studied[1–3]. Not surprisingly, a large body of literature exists describing the aberrations that occur as a result of surgical stress. These include a pronounced neuroendocrine response with increased sympathetic nervous system activity combined with changes in catecholamine, glucagon, growth hormone and insulin levels[3–6]. These hormonal changes are associated with a host of metabolic changes: in particular, enhanced mobilization of fat[5,7], enhanced protein catabolism and nitrogen loss[8,9], decreased glucose tolerance[6,10] and enhanced glucose turnover[1].

Despite this evidence regarding the immediate response to stress and/or surgery, there is a relative scarcity of information on the hormonal and metabolic changes that occur during convalescence from major uncomplicated surgery. Rose and King[11] pointed out that, 'Although knowledge of the internal biochemical milieu in man after operations has increased, relatively little effort has been directed towards increasing the understanding of the adaptation of man postoperatively to his external environment, including the routine demands of everyday life.'

Clinicians dealing with patients during their convalescence often find that many report feelings of tiredness, listlessness and lethargy for weeks and occasionally months after surgery. A number of findings have been associated with the convalescent state. These include impaired muscle function[12], weight loss[13], alterations in anthropometric data[13], decreases in serum transferrin[13], and impaired adaptabilty of heart rate to submaximal work[14], and some researchers have suggested the importance of the degree of surgical trauma and the duration of anaesthesia as causative factors for fatigue after surgery[15].

Although it is likely that the physical symptoms occurring during convalescence have a metabolic and hormonal basis, as is the case with the immediate response to stress and surgical trauma[1], few if any studies have measured energy kinetics, metabolic rates or hormonal levels in convalescent patients after discharge. Because of the uncertainties regarding the metabolic abnormalities, if any, associated with the convalescent state, we have performed paired studies measuring glucose and protein kinetics, metabolic rates and hormonal levels both preoperatively and during convalescence. Each patient was studied before surgery and again some 10 weeks after discharge from hospital.

Patients and methods

Paired isotopic studies were performed on four patients with histologically proven Dukes' A or B[17] adenocarcinoma of the colon or rectum and four patients with primary hyperparathyroidism. All patients were recruited from the general surgery wards at Auckland Hospital. Informed written consent was obtained in all instances The study was approved by the Ethical Committee at Auckland Hospital and the use of radioisotopes was approved by the National Radiation Laboratory of New Zealand See *Table 1* for patient details.

Nutritional intake

All patients were at least 12 h postabsorptive when studied. Basal kinetics were first determined, then the effect of glucose infusion was assessed by infusing glucose at 4 mg kg^{-1} min^{-1} for 2 h

CR, colorectal group; PTH, parathyroid group

Study design

All patients were studied before surgical resection and again on average 10 weeks afterwards. The studies were of two types and each was of 5 h duration necessitating four studies for each patient, two before surgery and two in the convalescent stage During the first 3 h of the studies isotope only was infused (period 1) and during the 2 h of period 2 the isotopic infusion was maintained and, in addition, glucose was infused at 4 mg kg^{-1} min^{-1} The isotopes were infused through a cannula in a forearm vein using an IVAC pump (Ivac Corp, San Diego, California, USA) Multiple blood samples were taken from a contralateral limb vein using another cannula over the last 30 min of period 1 and again over the last 30 min of period 2. Samples of expired air were also collected during these sampling periods when glucose oxidation was being assessed The air was collected into 6-litre anaesthetic bags and sampled for $^{14}CO_2$-specific activity. This method involves trapping 1 mmol CO_2 in a solution of hydroxide of Hyamine (Rohm and Haas Company, Philadelphia, USA) with 1 per cent phenolphthalein solution added as an indicator to mark when the solution was saturated with CO_2. After this the resultant solution had scintillation cocktail added and was counted on a liquid scintillation counter.

Indirect calorimetry was also carried out at this time using a Sybron Taylor Oxygen Analyser (UK) and an ADC CO_2 analyser (Hoddesden, UK)

Isotopic infusions

Two different types of infusion were employed on separate days.

To assess glucose kinetics and glucose oxidation To assess glucose kinetics and glucose oxidation we obtained [^{14}C]glucose and [6-^{3}H]glucose from Amersham laboratories (Amersham, UK) and these were infused as a primed constant infusion. The infusion rate for each isotope was approximately 1 nCi kg^{-1} min^{-1} with a priming dose of 80·1. The study was of 5 h duration with an infusion of glucose being employed during the last 2 h of the study (period 2) at a rate of 4 mg kg^{-1} min^{-1}. The bicarbonate pool was primed with $NaH^{14}CO_3$ as described previously[18].

To assess protein kinetics and net protein catabolism. To assess protein kinetics and net protein catabolism, [^{14}C]urea was infused throughout. Period 1 was of 3 h duration and in period 2 a glucose infusion was employed as in the protocol described above The infusion rate for [^{14}C]urea was 1 2 nCi kg^{-1} min^{-1} with a prime of 540 nCi kg^{-1} We have described both of these methods previously[18]

Analysis of samples

Blood samples were centrifuged to separate the plasma which was immediately chilled [^{3}H]- and [^{14}C]glucose and [^{14}C]urea specific activities were determined as described elsewhere[18]. Plasma insulin assays were determined using a radioimmunoassay and the cortisol concentrations with an Amerlex Cortisol RIA kit (Amersham, UK).

Calculations

Energy expenditure. From the calorimetry data and details of the patients' height, weight, age and sex, two further values were calculated The predicted energy expenditure (PEE) was calculated using the revised Harris–Benedict formula[19]. For male patients: PEE(kcal 24 h^{-1} = 5(height) + 13·7(weight) + 66 − 6·8(age), and for female patients· PEE(kcal 24 h^{-1}) = 1·85(height) + 9 6(weight) + 655 − 4·7(age).

The resting energy expenditure (REE) was calculated using the method of Weir[20]· REE(kcal 24 h^{-1} = 1440 min × (3 9 × V_{O_2} + 1·1 × V_{CO_2})

Isotopic calculations. The rate of appearance of glucose (Ra glucose) and Ra urea were calculated using the Steele equation as it applies to isotopic steady state[21]

$$\mathrm{Ra} = \frac{\text{infusion rate}}{\text{specific activity (SA)}} \tag{1}$$

Glucose oxidation (GO) was calculated as follows:

$$\mathrm{GO} = \frac{^{14}\mathrm{CO}_2 - \mathrm{SA} \times V_{\mathrm{CO}_2}}{[^{14}\mathrm{C}]\text{glucose} - \mathrm{SA} \times \mathrm{K}} \tag{2}$$

The percentage of glucose recycling was calculated as follows·

$$\text{percentage recycling} = \frac{\mathrm{Ra}(^{3}\mathrm{H} - {}^{14}\mathrm{C})}{\mathrm{Ra}(^{3}\mathrm{H})} \times 100 \tag{3}$$

The percentage of glucose uptake oxidized (GUO) was calculated as follows.

$$\mathrm{GUO} = \frac{\text{Glucose oxidation}}{\text{Ra glucose}} \times 100 \tag{4}$$

Net protein catabolism is derived from the Ra urea data and expressed as grams of protein per kilogram per day.

This methodology has been described elsewhere[18] including the calculation of the constant, K (equation 2)

Statistical analysis

The data obtained from the patients before surgical resection were compared with the convalescent data using the Mann–Whitney *U* test. The basal data in each study were compared to the corresponding data during glucose infusion also using the Mann–Whitney *U* test.

Results

As the basal values for both the colorectal and the parathyroid patients were similar, and the same trends were seen over 10 weeks of convalescence in both groups, the data have been pooled in this section for statistical analysis. However the raw data for each group can be seen in *Tables 2* and *3*, both in the basal state and during convalescence.

Energy expenditure

The PEE for the preoperative patients was 188 ± 7 kcal 24 h^{-1} (mean ± s.e.m.) and for the convalescent group it was 1360 ± 64 kcal 24 h^{-1}. The mean REE in the preoperative group was 1194 ± 62 kcal 24 h^{-1} which was not significantly different from the value obtained in the convalescent group: 1260 ± 46 kcal 24 h^{-1}.

Glucose metabolism

The basal rate of glucose production in the preoperative group was 14·8 ± 1·3 μmol kg^{-1} min^{-1} (mean ± s.e.m.) and following glucose infusion there was a 66·6 ± 12·2 per cent suppression of endogenous Ra glucose to 5·0 ± 0·4 μmol kg^{-1} min^{-1}. In contrast, in the convalescent patients the basal Ra glucose was significantly higher at 28·1 ± 2·5 μmol kg^{-1} min^{-1}/($P < 0·01$) and following glucose infusion there was a significantly smaller suppression of endogenous glucose production ($P < 0·05$) at 35·6 ± 5·6 per cent, resulting in an endogenous Ra glucose of 18·1 ± 1·7 μmol kg^{-1} min^{-1}. The percentage of glucose uptake oxidized in the preoperative patients was 35·5 ± 3·9 per cent. However, in the convalescent patients the percentage of glucose undergoing oxidation was significantly less at 21·5 ± 2·9 per cent ($P < 0·05$). Glucose recycling was 20·1 ± 10·0 per cent in the preoperative group. In the convalescent patients the percentage of glucose underging recycling was significantly higher at 52·9 ± 2·3 per cent ($P < 0·01$). See *Table 4* for details of glucose metabolism.

Urea kinetics and net protein catabolism

The mean (± s.e.m.) Ra urea in the preoperative patients was 8·0 ± 2·8 μmol kg^{-1} min^{-1}. The corresponding value in the same patients some 10 weeks later was not significantly different at 8·3 ± 1·7 μmol kg^{-1} min^{-1}. When net protein catabolism (NPC) was calculated from these data the preoperative NPC was

2·0±0·7 which is not significantly different from the convalescent value of 2·1±0·4 g kg^{-1} day^{-1}.

Plasma hormonal measurements

The mean (±s.e.m.) preoperative plasma insulin level was 3·2±2·3 microunits litre^{-1} and following glucose infusion this increased to 22·4±4·0 microunits litre^{-1} ($P<0{\cdot}01$) In the convalescent patients the basal insulin level was significantly higher ($P<0{\cdot}05$) at 14·0±3·8 microunits litre^{-1}. After glucose infusion in convalescent patients there was a proportionately smaller increase in plasma insulin to 22·0±4·2 microunits litre^{-1} ($P<0{\cdot}05$). The plasma insulin concentration during glucose infusion was not significantly different between the two groups.

Preoperatively the plasma cortisol concentration was 291±54 nmol litre^{-1} (mean±s.e.m.). The corresponding value in the convalescent patients was significantly higher at 496±75 nmol litre^{-1} ($P<0{\cdot}5$) (*Table 5*).

Discussion

The aim of our study was to define the metabolic profile of convalescent surgical patients and we have successfully documented a few of the probable myriad of changes occurring in these patients. The study groups were chosen because both were to have operative procedures of a similar duration although each had clearly differing degrees of tissue trauma It was our contention that if the convalescent state was associated with altered metabolic parameters then these would be relatively independent of the degree of tissue trauma. By seeing similar results in two groups with marked differences in tissue trauma we have excluded this as a variable.

Intuitively, both groups would be expected to benefit from surgery in a clinical sense, one because a malignant condition was being resected, the other because a functional adenoma resulting in symptomatic hypercalcaemia was being resected. It is important to note that the same trends were seen in both groups of patients. Although the sample number in both groups is relatively small it is reassuring to note that the preoperative data obtained in both the colorectal and parathyroid patients were similar to those we have previously published in larger series of patients These data can be seen in *Tables 2* and *3* and are obtained from References 16 and 22.

The metabolic rate in these patients was not greatly different from the predicted value, either before surgery or during convalescence. This is in accord with the work of Dempsey *et* *al.*[23] and findings of our own[16]. These data suggest that the patient with early colorectal cancer has a low or normal metabolic rate and we have previously shown patients with hyperparathyroidism to be normometabolic[22]. In addition, it is known that the basal metabolic rate does not change after moderately traumatic but uncomplicated surgery[24]. The slight decrease in predicted energy expenditure from preoperative to convalescent patients can be explained on the basis of the minor weight changes that occurred over this period. Metabolic rate is also a useful measure of surgical 'stress' and it is reassuring to note that during the study period the patients were normometabolic, that is we can deduce that the study itself was not associated with significant 'stress'.

Our key findings revolve around the marked alterations in glucose metabolism occurring in the convalescent setting. Glucose metabolism has been extensively studied in various conditions[16,18,22,25–27] and our present study documents major aberrations in glucose utilization. In particular, the convalescent patient appears to be unable to completely oxidize glucose to CO_2 and this is coupled with an increase in glucose recycling to lactate. Glucose oxidation decreases by approximately 40 per cent whereas glucose recycling more than doubles. This finding is consistent with the work of others who have demonstrated increased lactate production during convalescence[28]. The importance of this finding is that glucose recycling to lactate with subsequent Cori recycling is an energy-expensive process. Every 1 mol glucose metabolized to pyruvate/lactate yields 4 mol ATP. However, for that lactate to be metabolized back to glucose via the Cori cycle requires an additional 6 ATP resulting in a net energy imbalance. It is also important to realize that these changes are occurring in an essentially anaerobic part of metabolism and thus may not be reflected in an increased oxygen consumption. Furthermore, this finding of impaired glucose oxidation coupled with enhanced recycling is similar to what is seen in other forms of stress. For example, we have previously shown that severely septic patients have impaired glucose oxidation and enhanced substrate recycling[29], and Burke *et al.*[27] have demonstrated similar findings in traumatized patients.

The plasma cortisol concentrations were significantly higher in the convalescent patients, compared with the corresponding preoperative values, although on both occasions they were within the reference range quoted by our laboratory. All blood samples for cortisol assay were taken at the same time on each day of the study to allow for the diurnal rhythm of cortisol secretion. It is hard to determine how much emphasis to place on these cortisol results. The actions of cortisol are known to include: increased protein catabolism[30], increased hepatic glycogenolysis[31,32], increased gluconeogenesis[30] and increased Cori cycling[31,32]. In addition, cortisol is known to have an anti-insulin effect. It is likely that cortisol could be implicated in some of the observed changes seen in glucose metabolism as well as the diminished responsiveness of insulin secretion to glucose infusion seen in the convalescent patients.

The stimulus for the high basal insulin concentration seen in the convalescent patients is probably related, in part, to the elevated rates of glucose production in these patients. However, despite this elevated insulin concentration, the plasma glucose level was higher in the convalescent group, suggesting decreased insulin effectiveness. This finding of decreased effectiveness is consistent with what is seen in other forms of stress such as sepsis[29].

In summary, our data demonstrate that convalescent patients are metabolically abnormal 10 weeks after surgery. They have abnormalities in glucose metabolism and hormonal profile independent of changes in metabolic rate and protein metabolism. Inefficient pathways are prominent in these patients. In particular, there is an increase in anaerobic energy-expensive metabolism (glucose recycling) at the expense of oxidative aerobic metabolism. There are changes in stress hormone secretion and it is likely that the high cortisol concentration and decreased insulin secretory responsiveness are important in mediating the above changes. In contrast to what has been suggested by others, we have observed these abnormal findings in patients 10 weeks after surgery when all patients are managing at home independently. Metabolic changes following surgery appear to be unrelated to the degree of surgical trauma as evidenced by the similar changes seen in two different groups of patients.

Free-flap reconstruction of heel pad after femorotibial bypass salvage graft

R. J. McFarland, R. S. Taylor, F. Wood* and B. Mayou*

*Department of Surgery, Epsom District Hospital, Surrey and *Department of Plastic Surgery, St. Thomas' Hospital, London SE1, UK*

Correspondence to: Mr R. J. McFarland, Department of Surgery, St. George's Hospital, Blackshaw Road, London SW17 0QT, UK

The presence of full-thickness ischaemic necrosis of the heel with extensive exposure of the calcaneum has long been regarded by most surgeons as an indication for amputation. We describe such a patient in whom an aggressive team approach by vascular and plastic surgeons enabled the heel pad to be restored using microvascular surgical techniques.

Case report

A 78-year-old Polish man, who had been a lifelong smoker, had suffered progressive intermittent claudication in his right leg for 5 years. Nine months previously he had been investigated elsewhere, deemed unsuitable for vascular reconstruction, and had undergone lumbar sympathectomy without benefit.

When referred he could walk only a few yards and had developed a large painful ischaemic ulcer on his heel which was infected and necrotic, with exposed bone. The right femoral pulse was present but no distal pulses were palpable. Doppler studies showed an anterior tibial arterial pressure of 35 mmHg (pressure index 0·24) and no posterior tibial artery signal. Arteriography showed the superficial femoral artery to be blocked at the origin with occlusion of the popliteal artery both above and below the knee joint. The profunda femoris artery was patent but diseased and fed a number of small collaterals about the knee. The anterior tibial artery appeared to be patent throughout; the posterior tibial artery was patent but diseased in the distal part of its course and the peroneal artery was occluded.

Vascular reconstruction

Initially a graft to the anterior tibial artery was attempted as all investigations suggested that this was the most suitable recipient vessel. Accordingly, the anterior tibial artery was exposed via a lateral approach excising a segment of the fibula. However, the vessel appeared very diseased and when the arteriotomy was made there was almost no back bleeding and a fine 1 mm Parsonnet probe would not pass more than 7 cm distally. The posterior tibial artery was explored and found to be patent from a point 3 cm below its origin, accepting a 2 mm probe to a level just above the ankle. A 6 mm ringed polytetrafluoroethylene (PTFE) graft (GORE-TEX®, W. L. Gore and Associate, Incorporated) was placed in a subcutaneous tunnel and anastomosed to the common femoral artery in the groin and to the posterior tibial artery using our standard technique, which incorporates a vein gusset into both proximal and distal anastomoses. An operative arteriogram showed the anastomosis to be satisfactory and confirmed patency of the artery to the ankle.

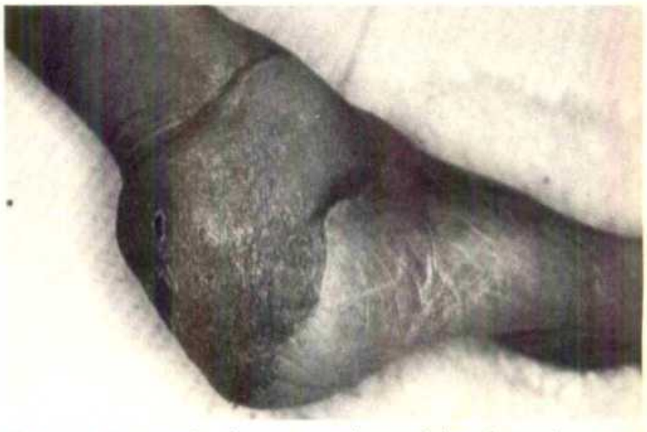

Figure 1 *Five months after surgery the arterial graft remains patent and the skin flap is healthy*

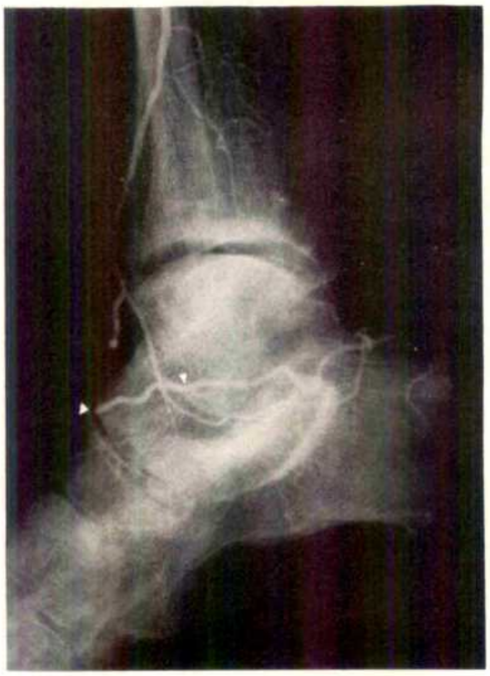

Figure 2 *Arteriogram at 6 months shows the radial artery supplying the skin flap (arrowed) taking origin from a dorsalis pedis artery which is filled retrograde from a vascular reconstruction to the posterior tibial artery*

Postoperatively, Doppler pressures were 80 mmHg in the posterior tibial and 130 mmHg in the dorsalis pedis (pressure indices 0·57 and 0·93, respectively) despite the latter vessel filling only indirectly through collaterals.

Plastic reconstruction

Although the fore-foot now appeared viable there was such extensive soft-tissue necrosis of the heel pad that after débridement the ulcer

0007–1323/89/020158–02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

measured 17 × 8 cm and the weight-bearing area of the calcaneum was exposed. Owing to the size and depth of the ulcer, full-thickness tissue replacement was felt to be necessary. Local flaps were small and the vascular supply in doubt; therefore, a free vascularized radial forearm flap was planned.

Five weeks after the vascular reconstruction the ulcer was stable and arteriography confirmed a patent graft with filling of the anterior tibial vessels.

A left radial forearm flap, 18 × 9 cm, was raised, and transferred to the right heel. An end-to-side anastomosis was performed between the radial artery and the dorsalis pedis artery, and end-to-end anastomoses were performed with both venae communicantes, using microsurgical techniques.

One month later the flap was trimmed and inset. Healing was complete at 6 weeks and the patient could be mobilized, taking full weight on his heel.

After 5 months the vascular graft was still patent and the foot, including the heel flap, was healthy and pain free (*Figure 1*). While the patient was being investigated for severe claudication in his other leg, the arteriogram shown in *Figure 2* was obtained. This shows the PTFE graft to the posterior tibial artery supplying the foot vessels and from these the dorsalis pedis artery from which the skin flap artery takes origin.

Discussion

A functioning vascular graft is of no value if the patient cannot walk on the salvaged foot. In our experience, patency rates of 90 per cent at 1 year can be obtained using externally supported PTFE prosthetic grafts to a suitable tibial or peroneal vessel provided that vein patches are incorporated in the anastomoses. The patch may be beneficial in reducing the compliance mismatch between prosthesis and artery, perhaps leading to increased flow, and reducing the severity of intimal hyperplasia. We believe that, in the absence of severe established gangrene, amputation should never be performed without first exploring the tibial vessels. As this case demonstrates, the arteriogram may not always give a true picture of the distal vessels. Even so, until recently this man's foot would have been regarded as unsalvageable as traditional skin grafts are not sufficiently robust to cover exposed bone on a weight-bearing area.

The free-flap technique provides substantial skin cover of even large areas of exposed bone without lengthy immobilization. The best source vessel in the foot is the anterior tibial as it is superficially situated and therefore accessible for the end-to-side placement of a 'wrap-around' graft for heel or sole. In our patient, even though the vascular graft was to the posterior tibial, the collateral flow to the dorsalis pedis artery was sufficient to support the flap.

In conclusion, the development of free-flap grafts means that extensive heel-pad necrosis should no longer be regarded as an indication to amputate. A distal vascular reconstruction which is successful in salvaging the rest of the foot can support a free-flap skin/muscle graft.

Treatment of a postoperative cholecystocutaneous fistula by an endoscopic stent

M. L. Sedgwick and M. E. Denyer

Gastrointestinal Unit, Seacroft Hospital, York Road, Leeds LS14 6UH, UK

Correspondence to: Dr M. E. Denyer

Gallstone retention and external biliary fistulae are important complications following biliary surgery and cause significant morbidity and mortality. We describe a patient with a cholecystocutaneous fistula associated with a retained common bile duct stone who was successfully treated by endoscopic papillotomy and insertion of a biliary endoprosthesis.

Case report

A 76-year-old man was admitted in August 1986 with acute cholecystitis. Ultrasonography revealed several stones in the gallbladder which was dilated with an impacted stone at the neck. He had a history of recent myocardial infarction, so surgery was felt to be inadvisable. Clinically he settled well with conservative management.

In March 1987 he was readmitted with a history of passing dark urine for 2 weeks and severe upper abdominal pain for 1 day. He was tender in the right hypochondrium and became jaundiced shortly after admission. Initially he was managed conservatively but 3 days after admission his white cell count had risen to $14{\cdot}6 \times 10^6$/l, with bilirubin 157 μmol/l (ULN* 19), alkaline phosphatase 350 international units (ULN 85) and AST* 46 units/l (ULN 35), and he underwent laparotomy.

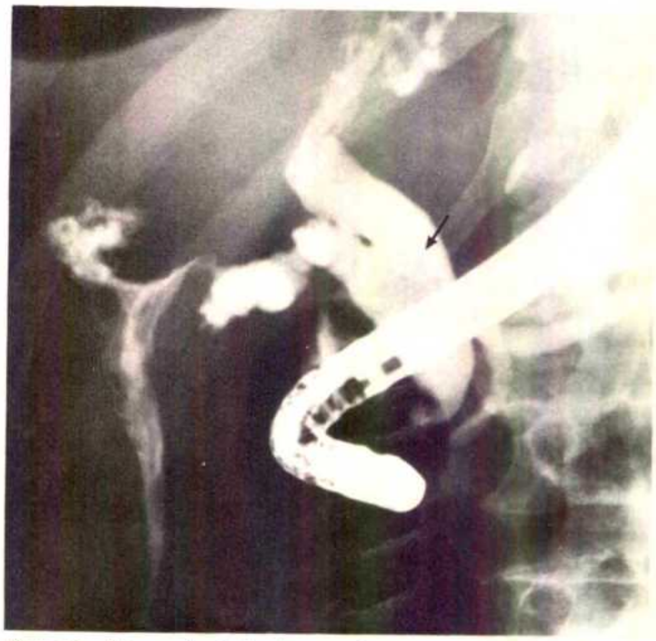

Figure 1 *Retrograde cholangiogram showing large common bile duct stone (arrowed) and cholecystocutaneous fistula*

A right paramedian incision revealed an inflammatory omental mass at the porta hepatis involving the first part of the duodenum and pylorus. A trial dissection failed to identify recognizable biliary anatomy; no bile leakage was noted. The abdomen was closed with a corrugated drain. Postoperatively his jaundice settled but he developed an external biliary fistula along the drain track, draining up to 500 ml of bile per day. This continued and 16 days postoperatively he was referred for endoscopic retrograde cholangiography (ERC), which showed a stone in the common bile duct impacted above the sphincter of Oddi and a cholecystocutaneous fistula (*Figure 1*). An adequate sphincterotomy was performed but the stone could not be extracted. Over the next week bile continued to drain via the fistula at a rate of 300–800 ml/day.

A repeat ERC showed that the stone had passed. To bypass the biliary leak a 10 Fr endoprosthesis 9 cm long was inserted endo-

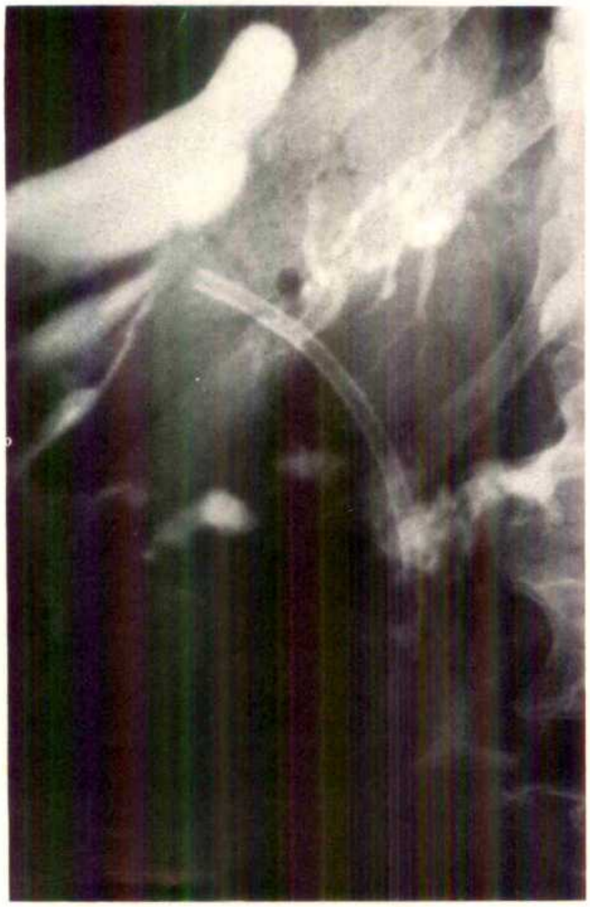

Figure 2 *Endoprosthesis inserted endoscopically with its proximal end above the cystic duct and distal end in the duodenum*

scopically with its proximal end above the cystic duct (*Figure 2*). There were no complications. Over the next 4 days the fistula dried up completely and his general condition improved. He was discharged home 1 week after insertion of the endoprosthesis. He remains well 1 year later, with no further jaundice or abdominal pain and no recurrence of his biliary leak.

Discussion

Biliary tract surgery is common and complications necessitated reoperation in 4·7 per cent of cases in one series, with considerable morbidity and mortality[1]. Of those cases requiring reoperation, 25 per cent have retained or recurrent biliary stones[1]. Biliary leaks are less common but are associated with higher morbidity and mortality.

Endoscopic sphincterotomy is an established method for removing retained stones with a 90 per cent success rate, a morbidity of 7–9 per cent and a mortality rate of 1 per cent or less[2]. Sphincterotomy has also been used successfully to treat postoperative external biliary fistulae[3]. Endoscopic stents have been of help in patients with post-cholecystectomy biliary–cutaneous fistulae[4,5] but not, to our knowledge, in patients with an intact gallbladder. The majority of enterocutaneous fistulae will close spontaneously provided that there is no distal obstruction. In our case a high-output fistula persisted after relief of the common bile duct obstruction by endoscopic sphincterotomy but resolved rapidly after insertion of a biliary endoprosthesis.

Severe sepsis leads to depression of the reticuloendothelial (RE) system with delayed bloodstream clearance of particulate matter and bacteria. Fibronectin may be an important opsonin of the RE system and low fibronectin levels often accompany severe sepsis in man. We have investigated the effect of prolonged intra-abdominal sepsis on plasma fibronectin concentrations and RE function. Serial plasma fibronectin concentrations were determined in rabbits for 2 weeks after either the induction of sepsis (appendix abscess) (n = 6) or laparotomy only (n = 6). RE function was measured at 2 weeks by determining the clearance kinetics and organ distribution of low dose technetium tin colloid (TTC). There was an early transient depression in plasma fibronectin values followed by elevated concentrations at 48–72 h which were more marked in the sepsis group. There was a delay in the blood clearance with reduced hepatic and increased bone uptake of TTC. We conclude that depletion of opsonic fibronectin is unlikely to be an important factor contributing to the impairment of RE function associated with intra-abdominal sepsis and that RE depression in septic animals is due to intrinsic Kupffer cell dysfunction.

Keywords: Fibronectin, reticuloendothelial function, intra-abdominal sepsis, intra-abdominal abscess

Sepsis remains a major cause of morbidity and mortality in surgical patients. The recent recognition of host defence failure and in particular that of the reticuloendothelial (RE) system during sepsis has generated interest in the underlying mechanisms. Failure of the RE system occurs during sepsis and may be due to several factors, including a deficiency of opsonins, an alteration in hepatic blood flow or intrinsic macrophage dysfunction. Fibronectin may be an important non-specific opsonin for the clearance of blood-borne particulate matter and bacteria and may play a protective part in conjunction with the RE system against microembolism of damaging particles (circulating bacteria and products of sepsis or tissue injury) which ultimately lead to end organ failure[1]. The demonstration of reduced fibronectin values during sepsis has led to trials of replacement therapy which have shown restoration of opsonin levels but have failed to show a significant improvement in survival[2]. Fibronectin concentrations have been raised in animal models of acute sepsis[3–5]. These severe models of sepsis have a very high early mortality and differ from the often slower, more insidious, onset of sepsis in surgical patients.

Low dose technetium tin colloid (TTC) can be used as an RE test agent to detect depression of RE-dependent blood clearance in the rabbit[6,7]. The aims of this study were to determine the effect of prolonged sepsis on plasma fibronectin concentrations and RE function, using a rabbit model of chronic intra-abdominal sepsis.

Materials and methods

Animal groups

Male New Zealand White rabbits (2·5–3·0 kg) were used.

Septic model. An intra-abdominal abscess was induced in the rabbit by devascularization of 80–90 per cent of the appendix. Animals were anaesthetized with intravenous sodium pentobarbitone (May and Baker Ltd., Dagenham, UK) and a midline laparotomy performed. The arcade of vessels between the appendix and small bowel and the main appendicular artery and vein were ligated and divided. The appendix was left *in situ* and the abdomen closed. Six animals underwent laparotomy only and acted as controls.

Measurement of plasma fibronectin

Blood was taken for plasma fibronectin estimation preoperatively, and postoperatively at 2, 4, 6, 9, 12, 15 and 24 h, and at 2, 3, 4, 6, 11 and 14 days. Blood was collected into paediatric size ethylene diaminetetraacetic acid polystyrene tubes, centrifuged immediately and the plasma removed for storage at −70°C. Plasma fibronectin concentrations were assayed by an immunoturbidimetric method[8] using commercially available antiserum. The results are expressed as the percentage change from the control (preoperative) value for each animal.

Measurement of RE function

RE function was measured 2 weeks after either laparotomy only or devascularization of the appendix. The rate of clearance of TTC from the bloodstream and its uptake into the liver, spleen, lungs and bone were determined. Animals were lightly anaesthetized with intravenous sodium pentobarbitone and a 1 ml bolus of TTC (Amerscan Hepatate II, Amersham International plc, Amersham, UK) was injected rapidly via an ear vein. The dose of TTC was approximately 0·0002 mg/kg labelled with 3·7 MBq technetium-99m. Serial blood samples were taken over 45 min from a vein in the contralateral ear. The animal was killed with an overdose of anaesthetic and the liver, spleen, right femur and lungs were removed. The activity of the blood and organs was measured using an LKB-Wallac 80 000 γ counter (LKB Instruments Ltd., Selsdon, South Croydon, UK). Blood clearance curves were constructed and analysed using a Hewlett Packard desk-top computer (HP9845B; Hewlett Packard, Wokingham, UK) running a pharmacokinetic program, modified to correct for radioactive decay and incorporating statistical analyses. The half-life of the clearance of TTC from the bloodstream was calculated from the first and fastest component of clearance. Uptake of TTC by the organs was measured by counting aliquots of homogenized liver and lung, and the whole spleen and right femur in the γ counter using 1 ml of TTC as a standard. The results are expressed as a percentage of the injected dose per gram of tissue.

Bacteriological cultures

Blood was taken for culture at 24 h and 14 days after operation.

0007–1323/89/020161–04$3.00 © 1989 Butterworth & Co (Publishers) Ltd

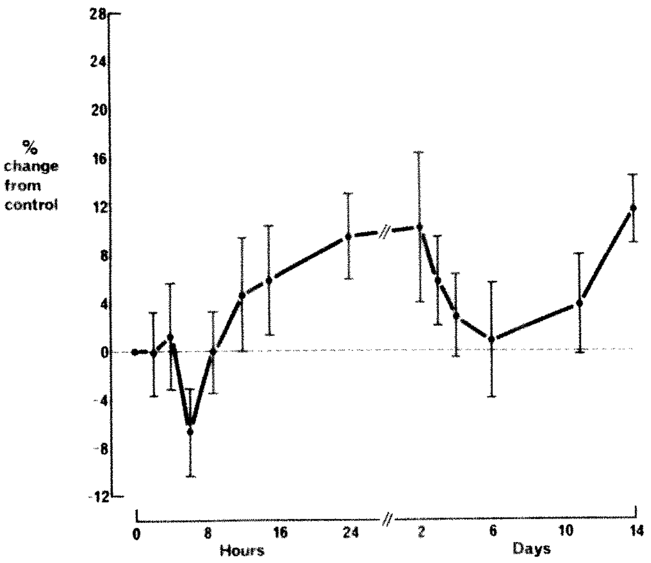

Figure 1 *Serial changes in plasma fibronectin concentrations in the laparotomy only group. The mean ± s.e.m. values are shown*

Cultures from the intra-abdominal abscess or peritoneum (laparotomy only animals) were taken when the animal was killed.

Statistical analysis

Results are expressed as the mean and standard error of the mean. Significance is tested by the Wilcoxon matched pairs signed rank or Mann–Whitney *U* test.

Results

The post-mortem finding in all the animals in the sepsis group was a solitary intra-abdominal abscess occupying the site of the appendix, surrounded by dense adhesions to other organs. Approximately 1 cm of the base of the appendix remained and appeared normal.

Bacteriology

In the sepsis group, five of six blood cultures taken at 24 h after the induction of sepsis were positive and grew a mixture of organisms. All blood cultures were negative at 14 days indicating that bacteriologically the sepsis was localized. Single species of bacteria were cultured from the pus in the intra-abdominal abscesses (*Escherichia coli*, $n=4$, and *Streptococcus faecalis*, $n=2$). All the blood and peritoneal cultures in the laparotomy only group were negative.

Plasma fibronectin

The plasma fibronectin results for the laparotomy only and sepsis groups are shown in *Figures 1* and *2* respectively. In the laparotomy only group (*Figure 1*), there was an initial depression in plasma fibronectin concentrations followed by an increase which reached a plateau at 24–48 h. After 1 week, plasma fibronectin concentrations had returned to normal but became elevated again at the end of the second week. In the sepsis group (*Figure 2*), there was a similar initial depression followed by a more marked increase in plasma fibronectin concentrations which did not peak until 72 h after the induction of sepsis. Plasma fibronectin concentrations returned to normal at the end of the first week but rose again during the second week.

The results for both groups are superimposed in *Figure 3* to illustrate the difference between the response to trauma and sepsis. The pattern of change in plasma fibronectin concentrations is similar for the two groups but the elevation occurring at 72 h in the sepsis group was significantly greater than the 48 h peak in the laparotomy only group ($P < 0.05$). The rise in plasma fibronectin during the second week was not statistically significant for either group.

Clearance kinetics

The clearance of TTC from the bloodstream is shown in *Figure 4*. There was a significant delay in the blood clearance of TTC in the sepsis group, as shown by the increase in the half-life.

Organ distribution

The distribution of TTC to the liver, spleen, bone and lungs is shown in *Figure 5a–d*. In the sepsis group, there was a reduction in the uptake of TTC by the liver but a significant increase in its uptake in bone. There was no difference between the two groups for the splenic uptake of TTC. Pulmonary localization of TTC was increased in the sepsis group, although this failed to reach statistical significance using the two-tailed Mann–Whitney *U* test.

Discussion

The results of this study demonstrate that there is an initial reduction in the concentration of plasma fibronectin after both surgical trauma and the induction of sepsis. This is a common finding in animals and man and occurs within hours of trauma. A reduction in plasma fibronectin concentrations has been found in the rat within 1 h of surgical (laparotomy and enterotomy)[9] or mechanical (Noble Collip drum) trauma[10] and

this has been shown to correlate with the blood clearance and liver uptake of gelatinized RE test lipid emulsion. Similarly, low plasma fibronectin concentrations have been found after elective operations in patients[11–13]. In these studies, fibronectin returned to preoperative values within 3–7 days.

The reasons for the reduction of plasma fibronectin shortly after injury may be: consumption of opsonin in the RE clearance of particulate material (collagenous debris and possibly bacteria) which enter the circulation after being produced by tissue injury; incorporation into fibrin clots[14]; a reduction in synthesis; or deposition in the healing wound[15–17]. Opsonic consumption and wound deposition are the most likely causes. Radiolabelled fibronectin has been shown to disappear rapidly from the circulation and to be deposited within 15 min of injection in the injured tissues of a rat trauma model[16]. Studies of critically ill surgical patients have reported a significantly greater reduction in fibronectin in patients with septic complications[18]. The reduction in plasma fibronectin concentrations in this study was similar for the sepsis and laparotomy only groups but occurred earlier in the septic animals which may reflect greater opsonic consumption or wound deposition of fibronectin.

The transient reduction in fibronectin was followed by a significant increase in its concentration in both groups. The peak level of plasma fibronectin was not only significantly greater in the septic animals but also occurred later than the peak level in the laparotomy only group. One other study has measured the temporal response of fibronectin over a 2-week period in rats made septic by the intraperitoneal placement of opened ileum taken from another animal[4]. These workers also found that the increase in fibronectin occurred later than in the control group. This difference may be due to greater consumption of fibronectin in the septic animal.

Restoration of fibronectin levels in the post-injury period has been correlated with recovery of RE function[19]. The increase in plasma fibronectin above pre-injury levels may serve to augment local defence as well as the RE clearance of circulating bacteria and products of sepsis or tissue injury. This hypothesis may be valid for animals that undergo laparotomy only but the elevation of plasma fibronectin in animal models of sepsis has been shown to be associated with persistent impairment of RE function[3,5]. Lanser and Saba suggested that the increase in fibronectin may precede the recovery of RE phagocytic function[20] but, as this study has shown, RE functional depression is still present at 2 weeks. Grossman *et al.* found that fibronectin values in septic rats returned to normal by the end of the first week but remained elevated in non-surviving animals until death[4]. Therefore, in animal models of sepsis there seems to be an inverse relationship between fibronectin levels and RE function that contrasts with septic surgical patients in whom low levels correlate with impaired RE function.

The return to normal values of plasma fibronectin by the end of the first week may have coincided with the septic, necrotic focus being 'walled off' and thereby reducing the amount of collagenous debris and bacteria reaching the liver and systemic circulation. Further fluctuations in fibronectin concentrations may be related to the healing process. Fibronectin is important for initiating repair[21] and is a major component present in mature granulation tissue at 14 days after injury[17]. The role of fibronectin in local defence might be to augment phagocytosis by neutrophils and peritoneal macrophages to aid the clearance of fibrin, tissue debris and bacteria and thus inhibit their systemic absorption[20]. Delayed absorption of bacteria or exotoxin may aid immediate survival while inefficient absorption may lead to abscess formation and a greater long-term mortality rate.

It is concluded that the RE failure found in septic animals is due to intrinsic Kupffer cell dysfunction. This depression of RE function results in delayed RE dependent blood clearance and increased uptake of particulate matter by other RE cells such as the bone marrow macrophages. The reason for the biphasic response of plasma fibronectin to sepsis is not known but several factors may be important. These factors include consumption of plasma fibronectin and increased release or synthesis of the protein. Further work is needed to establish the mechanisms of RE cellular failure and fibronectin changes during sepsis.

Effect of nutritional status on acute phase protein response to elective surgery

A. M. Cruickshank, D. T. Hansell†, H. J. G. Burns† and A. Shenkin

Department of Biochemistry and †Department of Surgery, Royal Infirmary, Glasgow, G4 0SF, UK

Correspondence to:
Dr A. M. Cruickshank

The aim of this study was to assess the effect of nutritional status on the acute phase protein response to elective surgery. Matched pairs of patients with gastric or colorectal cancer were studied. Undernourished patients (body-weight <80 per cent of ideal and triceps skinfold thickness <65 per cent of standard) were matched with controls (body-weight >95 per cent of ideal and *triceps skinfold thickness >80 per cent of standard) for age, sex, type of pathology and surgery. Blood samples taken preoperatively and on days 1–5 after operation were analysed for C-reactive protein, α_1-antitrypsin, α_1-acid glycoprotein, albumin, prealbumin and transferrin. There was no significant difference in any of the preoperative protein concentrations between the two groups although undernourished patients tended to have lower transferrin concentrations (mean ± s.e.m., 2·2 ± 0·3 g/l) than the control group (2·9 ± 0·1 g/l). C-reactive protein response was significantly smaller in the undernourished group than in the control group* (P = 0·05, *Mann–Whitney* U *test). The responses of the other acute phase proteins did not differ between the two groups. There was no difference in the length of hospital stay after operation when undernourished patients (mean ± s.e.m., 17·7 ± 3·0 days) were compared with controls (14·3 ± 3·6 days). Undernourished patients therefore have an attenuated C-reactive protein response to elective surgery. The significance of this in relation to morbidity and mortality in severely ill patients requires further investigation.*

Keywords: Acute phase proteins, C-reactive protein, nutritional status

Following tissue injury in humans, a variety of physiological and biochemical responses have been described[1]. Of particular interest is the significant alteration that occurs in the serum concentrations of certain proteins[2,3]. These proteins are collectively known as acute phase proteins (APPs) and most of them are synthesized by the liver. After trauma the plasma levels of these proteins may increase (positive APPs) or decrease (negative APPs). Although many aspects of this protein response remain unclear and our understanding of the functions and biological significance of these proteins is limited, it is generally assumed that they perform a protective role by limiting tissue damage and promoting repair and healing[4]. It is possible therefore that any condition which impairs the APP response (APPR) may limit ability to survive injury.

Few studies have examined the relationship between nutritional status and APPR in humans. If poor nutritional status resulted in impairment of the APPR, then the apparent relationship between malnutrition and increased postoperative morbidity[5,6] might, in part, be explained. The object of the present study was to determine the effect of undernutrition on the ability of patients to mount an APPR to elective surgery.

Patients and methods

Twelve patients undergoing elective resection of either gastric or colorectal cancer were identified for study. Preoperative nutritional status was assessed using anthropometry. Patients were considered to be undernourished if body-weight was <80 per cent of ideal[7] and triceps skinfold thickness was <65 per cent of the standard[8]. Patients with clinical evidence of oedema were excluded. Undernourished patients were matched with normally nourished controls whose body-weight was >95 per cent of ideal and triceps skinfold thickness was >80 per cent of standard. These patients were matched for age, sex, pathology and surgery. Patients were excluded if any complications occurred at operation or within the period under study. Six pairs completed the study (two female, four male; two gastric, four colorectal carcinoma; *Table 1*). Venous blood samples were taken preoperatively and on days 1–5 after surgery.

Each blood sample was analysed for: C-reactive protein, (TDX system, Abbott Diagnostics Inc, North Chicago, Illinois, USA); α_1-antitrypsin, α_1-acid glycoprotein and transferrin (antisera and standard from Atlantic Antibodies, Scarborough, Maine, USA using the Encore Chemistry System, Baker Instruments, Windsor, Berkshire, UK); prealbumin (reagents from Serotec, Bicester, Oxon, UK); and albumin (by the bromocresol green method on a Hitachi 704, BCL, Lewes, East Sussex, UK).

The APPR after surgery in the undernourished group was compared with the response in the matched control group. Statistical analysis of results was carried out using a paired Student's *t* test and Mann–Whitney *U* test.

Results

There was no difference in the length of postoperative hospital stay between undernourished patients (mean ± s.e.m., 17·7 ± 3·0 days) and controls (14·3 ± 3·6 days).

Preoperatively there was no significant difference in protein

concentrations between the two groups, although undernourished patients tended to have lower transferrin concentrations (*Table 2*).

Serum levels of C-reactive protein rose in both groups after surgery. Maximum levels were reached after approximately 48 h and were significantly lower in the undernourished group (mean±s.e.m., 171·0±23·6 mg/l) than in the control group (221·5±24·6 mg/l; $P<0{\cdot}02$, paired *t* test; *Figure 1*). Moreover the total response to C-reactive protein (area under curve) was significantly lower in undernourished patients (mean±s.e.m., 4728±749) than in the controls (6395±681; $P<0{\cdot}05$, paired *t* test). The significance of this observation was confirmed by nonparametric unpaired statistical analysis (control median, 6884; undernourished median, 4915; $P=0{\cdot}05$, Mann–Whitney *U* test).

In both groups α_1-antitrypsin and α_1-acid glycoprotein levels rose significantly ($P<0{\cdot}001$ and $P<0{\cdot}01$ respectively, paired *t* test) to reach a maximum at approximately 4 days after operation (*Figures 2* and *3*). There was no difference between the two groups in the responses of either of these proteins.

The responses of the negative APPs, namely albumin, prealbumin and transferrin, did not differ between the two groups (*Table 3*).

Discussion

Undernourished patients had an attenuated C-reactive protein response whereas the response of the other APPs (negative and positive) did not differ between the undernourished group and controls. The increase in serum concentration of the APPs following injury is primarily as a result of increased hepatic synthesis, although there is evidence to suggest that α_1-acid glycoprotein is produced by other cells[9]. C-reactive protein is synthesized exclusively by hepatocytes, and tissue injury results in the progressive recruitment of increasing numbers of hepatocytes to synthesis[10]. In our patients, the magnitude and rate of increase of C-reactive protein concentration were approximately tenfold greater than those of α_1-antitrypsin and α_1-acid glycoprotein concentrations, and thus hepatic synthesis of C-reactive protein may be more sensitive to lack of substrate than is the synthesis of other APPs. Muscle breakdown is thought to

be related to the acute phase response[11,12]. Thus depleted skeletal muscle protein stores (as reflected by decreased arm muscle circumference, *Table 1*) may cause impaired substrate supply to the liver and directly affect the liver acute phase reactant synthetic capacity[13].

Our results differ from those of Dominioni *et al.*[14] who looked at the APPR to gastrectomy in 'undernourished' patients and controls with gastric cancer and found that α_1-acid glycoprotein was the only APP affected by malnutrition, the peak concentration being lower in the 'undernourished' group. However, in that study the sole criterion for classifying a patient as undernourished was a serum albumin concentration <32 g/l. Another study which examined the relationship between nutritional status and acute phase mediators, and which suggested that patients with mild to moderate malnutrition had an intact ability to produce leucocyte endogenous mediator after elective surgery, also used serum albumin concentrations as a marker of nutritional status[15]. It is now generally accepted that such use of serum albumin concentration is invalid. The form of undernutrition most often present in hospital patients in the developed world is moderate protein-calorie malnutrition which is poorly reflected by serum albumin concentration[16]. Serum albumin concentration is more dependent on its distribution between intravascular and extravascular fluid compartments and on hydration state than on any change in its synthetic or catabolic rate[17]. We chose to use anthropometric criteria to diagnose protein-calorie malnutrition. Our finding of similar preoperative albumin concentrations in the undernourished and control groups confirms that serum albumin concentration is a poor marker for protein-calorie malnutrition.

The acute phase response is brought about by a variety of as yet incompletely characterized regulatory mediators which include interleukin 1[18], and cachectin[19]. More recently interleukin 6 (originally described as interferon B_2) has also been shown to be an important mediator of the APPR and to be identical to hepatocyte stimulating factor 1[20]. In addition to affecting hepatic protein synthesis directly it is likely that undernutrition affects these mediating factors, a premise supported by recent work in protein-depleted guinea-pigs[21]. Bauman *et al.*[19] have shown that in rat hepatoma cells distinct sets of acute phase plasma proteins are stimulated by separate human hepatocyte stimulating factors (HSFI and HSFII) and with a different sensitivity relative to interleukin 1 and cachetin stimulation. If some of these factors are more sensitive to undernutrition than others, this could partly explain why undernourished patients in our study showed normal responses of some APPs but impaired response of C-reactive protein.

In this study, the attenuated C-reactive protein response of the undernourished group was not associated with any difference in outcome in terms of length of postoperative hospital stay. Patients who developed complications were specifically excluded from our study to eliminate any factors that might affect APP levels. One may postulate that had sepsis occurred, then patients with an impaired C-reactive protein response may have had a poorer prognosis. Indeed an association between an impaired APPR in severely septic surgical patients and poor outcome has been demonstrated[22]. Although the precise function of C-reactive protein is not known, it is likely to be beneficial because of the stable evolutionary conservation of this protein. Human C-reactive protein is an effective precipitin and agglutinin of soluble and particulate ligands, and is probably involved in activation of the classical complement pathway[23].

In summary, we found that undernourished patients had an attenuated C-reactive protein response to elective surgery although the responses of other APPs were unaffected. We conclude that undernutrition does affect aspects of the APPR in humans. The clinical significance of this finding remains to be determined.

Appendicitis complicating meconium ileus equivalent

J. A. P. Rimmer, J. M. Gilbert and T. G. Allen-Mersh

Academic Surgical Unit, St. Stephen's Hospital, Chelsea, London SW10 9TH, UK
Correspondence to: Mr J. A. P. Rimmer

Adults with cystic fibrosis are susceptible to partial or complete bowel obstruction induced by abnormally viscid mucofaecal material in the terminal ileum and caecum. This condition, which has been termed 'meconium ileus equivalent'[1], is often associated with cessation of pancreatic enzyme replacement or upper respiratory infection[2]. Complications of meconium ileus equivalent include intussusception and volvulus[1]. We report a case of an adult with cystic fibrosis in whom appendicitis was associated with obstruction of the appendix lumen by abnormally viscid mucofaecal material.

Case report

A 24-year-old man with cystic fibrosis, which had been diagnosed at 1 year of age, presented with a 1 month history of recurrent central and lower abdominal pain. The onset of pain coincided with changing from Pancrex V (Paines and Byrne Ltd., UK) to 'Creon' (Duphar Laboratories Ltd., UK) oral pancreatic enzyme supplement, which had also resulted in constipation. Three days before admission the pain became more severe, and localized to the right iliac fossa. The clinical features of fever, central abdominal pain shifting to the right iliac fossa followed by guarding and rebound tenderness, and the presence of a leucocytosis suggested appendicitis, but could also have been the result of meconium ileus equivalent syndrome[1]. At operation an acutely inflamed, distended appendix was removed and the patient made an uneventful recovery. The appendix measured 2 cm in diameter and 7·5 cm in length, and the lumen was filled with abnormally viscid mucofaecal material. Histological examination showed features of acute suppurative appendicitis and confirmed that the lumen was distended with mucofaecal material (*Figure 1*).

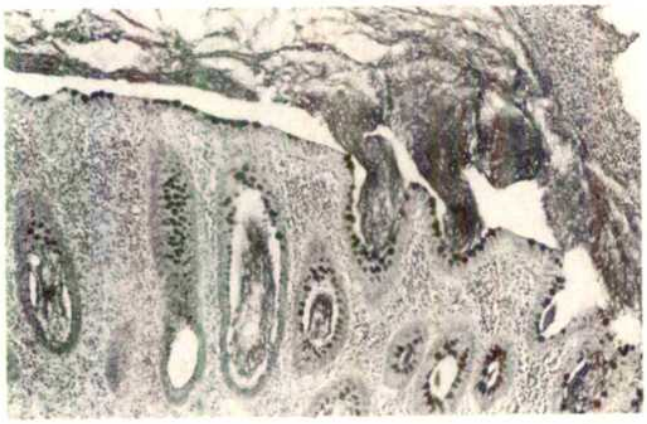

Figure 1 *Photomicrograph of a cross-section of the appendix showing acute inflammation and distension by mucofaecal material (periodic acid–Schiff, magnification ×8)*

Discussion

Acute appendicitis is thought to develop in 0·5–1·6 per cent of patients with cystic fibrosis[2–4]. The diagnosis is usually made late and is associated with a high incidence of abdominal and pelvic sepsis, resulting in a mortality rate of up to 33 per cent[3]. It has been suggested that the lower incidence of appendicitis in association with cystic fibrosis, compared with that in the general population (7 per cent)[3] may be the result of intraluminal mucofaecal material protecting the appendix from inflammation. However, this difference could be explained by the tendency to late diagnosis of appendicitis in patients with cystic fibrosis[3] resulting in spontaneous resolution without diagnosis in some less severe cases, and also by the difference in life expectancy between cystic fibrosis patients and the general population.

In our patient the lumen was filled with putty-like mucofaecal material and the appendix was inflamed. There was no evidence of a faecalith, worm, food debris, congenital band or any of the other known causes of acute appendicitis[5]. This, and the recent alteration in bowel habit produced by the change in enzyme supplement, suggests that the mucofaecal material contributed to the development of appendicitis. Thus appendicitis appears to have been a complication of meconium ileus equivalent.

Abdominal pain is a common complaint in patients with cystic fibrosis and, in addition to meconium ileus equivalent, may be a consequence of malabsorption, acute pancreatitis, gallstones, or peptic ulceration[6]. Thus, diagnosis of the acute abdomen in cystic fibrosis can be difficult and may lead to late diagnosis of appendicitis[3].

With increased life expectancy[1,7], appendicitis can be expected to occur more frequently in patients with cystic fibrosis. The dogma that appendicitis in cystic fibrosis is rare may be dangerous. At best the evidence for this is not conclusive and such a view may encourage a tendency to late diagnosis and increased morbidity in these patients.

Anergy in patients with biliary lithiasis

A prospective study was carried out in 428 subjects (212 controls and 216 patients) to evaluate the delayed cell-mediated immune response preoperatively in patients with biliary lithiasis. The delayed hypersensitivity response was assessed by a Multitest and subjects were classified as immunocompetent, relatively anergic or anergic. Significant differences were found between control subjects and patients with cholelithiasis compared with those with acute cholecystitis ($P<0{\cdot}01$), *non-icteric choledocholithiasis* ($P<0{\cdot}01$) *and choledocholithiasis with jaundice* ($P<0{\cdot}05$). *There were also differences between patients with icteric and non-icteric choledocholithiasis* ($P<0{\cdot}02$). *Seven possible causative factors for anergy were evaluated: a haemoglobin concentration of* $\leqslant 12$ *g/l and a haematocrit of* $\leqslant 35$ *per cent were related to the appearance of anergy and relative anergy in patients with acute cholecystitis. Bilirubin levels* $\geqslant 34$ *μmol/l were found in 60 per cent of patients with choledocholithiasis and relative anergy and in 80 per cent of those who were anergic* ($P<0{\cdot}001$). *These results show a high incidence of failure of the cell-mediated immune response in patients with acute cholecystitis (71 per cent) and icteric choledocholithiasis (82 per cent). In the latter, jaundice appears to be associated with this failure. A close correlation between relatively anergic and anergic state and the development of postoperative septic complications was found.*

The rates of postoperative infection secondary to surgery performed to treat biliary lithiasis depend on the site of the gallstone(s) in the biliary tract. Thus, while in uncomplicated cholelithiasis postoperative infections are rare, their incidence increases considerably if a stone becomes impacted at the gallbladder's outlet, producing acute cholecystitis, or if it has migrated to and obstructed the common bile duct.

Anergy has been established in several studies[1–7] as a risk factor for the development of postoperative infection. Therefore, we have evaluated preoperatively the status of the delayed cell-mediated immune response in patients with lithiasis of the common or accessory biliary ducts.

Patients and methods

A 3-year (1984–86) prospective study was undertaken in 428 subjects, 212 controls and 216 patients, with biliary lithiasis with a view to analysing the cell-mediated immune response The control group consisted of 110 men (51·9 per cent) and 102 women (48·1 per cent). All were in good general health, had no history of recent weight loss and none was on medication. Ages ranged from 21 to 82 years (mean age ± s.d 44·2 ± 14 9 years)

The patient group was composed of 216 subjects with biliary lithiasis and comprised 135 with uncomplicated cholelithiasis, 38 with acute cholecystitis, 21 with non-icteric choledocholithiasis and 22 with icteric choledocholithiasis. The preoperative diagnosis of gallstones and acute cholecystitis was made by history and physical examination, leucocyte count, plain X-ray film of the abdomen and ultrasonography (with or without additional intravenous cholangiography) There were 63 men (29·2 per cent) and 153 women (70·8 per cent), ranging in age from 14 to 91 years (mean age ± s.d. 52·4 ± 16·3 years) None had received radiation therapy or chemotherapy or had undergone other surgery during the 3 months preceding surgery.

The Multitest* technique was used to evaluate the delayed cell-mediated immune response. This method of instant multipuncture involves injection of seven antigens and one glycerin control. The antigens were each given in a dose of 0 03 ml and consisted of tetanus, 550 000 Merieux units/ml; diphtheria, 1 100 000 Merieux units/ml; *Streptococcus* (group C), 2000 Merieux units/ml, tuberculin, 300 000 units/ml; *Candida*, 2000 Merieux units/ml; *Trichophyton*, 150 Merieux units/ml; and *Proteus mirabilis*, 150 Merieux units/ml. The control was a 70 per cent weight/volume solution of glycerol.

Antigens were injected in the volar surface of the forearm and results were read at 48 h. The response was considered positive when the mean of the greater and lesser diameters was >2 mm. The sum of the mean response to the seven antigens constituted each patient's 'score'. There were three groups of responses· immunocompetent, with a score >10 mm in men and >5 mm in women, relative anergy, with a score of 2–10 mm in men and 2–5 mm in women; and anergy, with a negative response or a score <2 mm. All patients were hospitalized for 2 days after antigen administration, and the delayed hypersensitivity test was performed on all patients preoperatively

The patients were monitored daily for clinical signs of a major septic complication during the postoperative period and on an outpatient basis at 4 weeks after discharge. Major sepsis was defined as intra-abdominal abscess, bacteraemia, lung infection, anastomotic fistula, septic shock, and death attributed to septic causes

Seven possible causative factors for anergy were studied age $\geqslant 60$ years; serum albumin $\leqslant 30$ g/l, leucocyte count $\geqslant 9000/\text{mm}^3$, haemoglobin $\leqslant 12$ g/l, haematocrit $\leqslant 35$ per cent, total bilirubin $\geqslant 34$ μmol/l, and presence of cirrhosis To this end, blood was drawn from all patients for analysis at the time of antigen administration.

In those patients in whom the gross appearance of the liver during surgery was suggestive of cirrhosis, a biopsy was taken for subsequent histological analysis

Statistical analysis was performed by means of the χ^2 test with the Yates' correction. Values of $P<0{\cdot}05$ were considered significant

Results

Delayed hypersensitivity response

No differences were seen in the delayed hypersensitivity response between controls and patients with uncomplicated cholelithiasis (*Table 1*). In the case of relative anergy there was a statistically significant difference between patients with uncomplicated cholelithiasis and those with acute cholecystitis ($P<0{\cdot}01$) and icteric choledocholithiasis ($P<0{\cdot}05$) Similarly, with regard to the anergy response, there was a significant difference between uncomplicated cholelithiasis and acute cholecystitis ($P<0{\cdot}001$) and non-icteric and icteric choledocholithiasis ($P<0{\cdot}01$ and $P<0{\cdot}001$ respectively). A pronounced difference was found between patients with non-icteric choledocholithiasis and those with jaundice ($P<0{\cdot}02$). When the anergic and relatively anergic patients were combined there

was a statistically significant difference between patients with uncomplicated cholelithiasis and those with acute cholecystitis ($P<0\cdot001$), uncomplicated cholelithiasis and non-icteric choledocholithiasis ($P<0\cdot01$), uncomplicated cholelithiasis and icteric choledocholithiasis ($P<0\cdot001$), and non-icteric and icteric choledocholithiasis ($P<0\cdot01$).

The patients with the greatest alteration of the delayed cellular immune response were those with choledocholithiasis and jaundice, as 82 per cent of the 22 patients in this group were either anergic or relatively anergic.

Anergy: risk factors

Of the seven risk factors for anergy, three had no statistical relationship with its development, namely age ≥60 years (*Table 2*), serum albumin ≤30 g/l (*Table 3*), or leucocyte count ≥9000/mm^3 (*Table 4*).

In patients with acute cholecystitis, haemoglobin values of ≤12 g/l were related to relative anergy ($P<0\cdot01$) or anergy ($P<0\cdot05$; *Table 5*). In these same patients, relative anergy was significantly associated with a haematocrit of ≤35 per cent ($P<0\cdot01$; *Table 6*).

Values are number of patients with serum bilirubin concentration ⩾34 μmol/l over the total number of patients in each category. Values in parentheses are percentages * $P<0\cdot01$, $\chi^2=7\cdot82$, *versus* immunocompetent; † $P<0\cdot02$, $\chi^2=6\cdot28$, *versus* immunocompetent

Regarding jaundice, of those patients with choledocholithiasis, 60 per cent of those with relative anergy and 81 per cent ($P<0\cdot01$) of those with anergy had bilirubin values ⩾34 μmol/l (*Table 7*).

In three patients, cirrhosis was histologically confirmed. One had uncomplicated cholelithiasis, another had non-icteric choledocholithiasis and a third had icteric choledocholithiasis. Though all three were anergic, this was too low an incidence of cirrhosis to permit valid statistical conclusions to be drawn.

Relationship between anergy and postoperative sepsis

Of the 216 patients studied, 198 underwent surgery. Of these, 138 were immunocompetent, 28 showed relative anergy and 32 were anergic. Of the 138 immunocompetent patients only two (1·4 per cent) developed major septic complications in the postoperative period (one bacteraemia and one right subphrenic abscess). Of the 28 patients with relative anergy, four (14 per cent) had major septic complications (three bacteraemia and one right subphrenic abscess). Similarly, of the 32 anergic patients, five (16 per cent) had postoperative sepsis (two bacteraemia and three septic shock and death (anergic *versus* immunocompetent patients, $\chi^2=19\cdot29$, $P<0\cdot001$; relatively anergic *versus* immunocompetent patients, $\chi^2=11\cdot9$, $P<0\cdot001$). Of the nine relatively anergic and anergic patients who developed postoperative septic complications, eight were jaundiced.

Discussion

Anergy, defined as a failure of the delayed cell-mediated immune response, has been emphasized in several studies[1–7] as a factor in the development of postoperative sepsis. We have also confirmed this as a risk factor for postoperative sepsis in a study of 503 patients[8] and showed a close correlation between the presence of preoperative anergy or relative anergy and the development of postoperative infection. Since biliary lithiasis is one of the most common problems encountered in surgery, we investigated delayed cellular immunity status preoperatively in patients with lithiasis of the common and accessory bile ducts.

The results of the present study stress that patients with uncomplicated cholelithiasis have only a slight risk of developing anergy, the risk being the same as that of healthy controls. In patients with stones that migrate to but do not obstruct the common bile duct, the risk increases, but the greatest risk is found in patients with acute cholecystitis and especially in those with obstructive choledocholithiasis; 71 and 82 per cent respectively of these groups of patients are anergic or relatively anergic. This fact could explain the high rate of infection in patients with acute cholecystitis and in those with obstructive choledocholithiais. Stone *et al.*[9] established that the rate of surgical infection in chronic cholecystitis was 8·9 per cent as opposed to 17 per cent in acute cholecystitis. Hollands *et al.*[10] found a surgical wound infection rate of 8 per cent in patients with no obstruction of the gallbladder. The serious risk that infection poses has been pointed out by several authors[11–15] who noted that high infection rate increases surgical morbidity and mortality. The bacteriological aspects of these infections have been discussed in several studies[16–21].

With the relationship between anergy and acute cholecystitis on the one hand, and choledocholithiasis (and especially obstructed choledocholithiasis) on the other, the factors responsible for this anergy must be determined. In our study we have elected to analyse seven possible factors, namely advanced age[4,22,23], hypoalbuminaemia[24–27], leucocytosis[28], decreased haemoglobin concentration and haematocrit[29–31], cirrhosis[32], and hyperbilirubinaemia. We have demonstrated that neither advanced age, hypoalbuminaemia nor leucocytosis were responsible for anergy, although elsewhere[33] we did find a correlation between these parameters and anergy in other diseases. In the present series haemoglobin ⩽12 g/l and haematocrit ⩽35 per cent were related to the presence of anergy or relative anergy in patients with acute cholecystitis. Anergy was present in the three patients in whom cirrhosis was demonstrated, but the limited number of cases did not permit statistical conclusions to be drawn. However, a close association between an increase in serum bilirubin levels and the develoment of anergy or relative anergy was found in patients with choledocholithiasis; 60 per cent of the relatively anergic and 81 per cent of the anergic patients had a total bilirubin ⩾34 μmol/l. These rates of anergy are similar to those found by us in a previous study in which we examined the incidence of anergy in patients with jaundice due to various different disorders including tumours of the biliary tract and head of the pancreas[34].

Despite the fact that Brown *et al.*[35] and Ausobsky *et al.*[36] did not find any correlation between the presence of anergy and postoperative sepsis in surgical patients, an increasing number of authors are now reporting such a relationship. Our study confirms a close correlation between state of relative anergy and anergy and major postoperative sepsis. Although the rate of septic complications was similar in the relatively anergic and anergic groups, those of the anergic group were more serious, with three deaths due to sepsis compared with none of septic origin in either relatively anergic or immunocompetent patients.

Pylorus-preserving pancreatectomy: functional results

D. R. Hunt and
R. McLean*

*University Department of Surgery, and *Department of Nuclear Medicine, The St. George Hospital, Kogarah, New South Wales 2217, Australia*

Correspondence to
Professor D. R. Hunt

The pylorus-preserving technique is reported as improving the functional results of pancreatectomy but it is complicated in the early postoperative period by delayed recovery of gastric function in a proportion of patients. We have examined early and late gastrointestinal function in a prospective study of 16 patients having this procedure. The late results appear better than reported results for conventional Whipple resection and the delay in early recovery does not appear to have any late sequelae, provided that it does not require gastric bypass for relief.

Keywords: Pancreatectomy, pylorus preservation, gastrointestinal function, gastric emptying

When Whipple *et al.*[1] reported in 1935 their first successful pancreaticoduodenectomy, the first part of the duodenum was transected and no portion of the stomach removed. However, in a paper published in 1945[2], Whipple described a modification of the original operation and this modification now bears his name. One of the changes from the original description was the addition of a 50 per cent gastrectomy. Although most current texts state that this is done to prevent ulceration, Whipple admitted that 'this was a mistake': the tumour was thought to be arising from the posterior wall of the antrum and only after the stomach was transected was the origin from the pancreas defined. In the following years, numerous techniques and modifications were described but it is worth noting that Kausch[3] and Watson[4] reported single cases where the pylorus was preserved and four of the 30 cases reported by Waugh and Clagett from the Mayo Clinic[5] had pyloric preservation. Notwithstanding, the Whipple technique became the standard curative procedure for carcinoma of the head of the pancreas and ampullary region for 35 years.

In 1978, Traverso and Longmire[6] reported two patients requiring pancreaticoduodenal resection in whom the stomach and pylorus were preserved and the duodenal bulb was anastomosed end-to-side to the jejunum. This operation has subsequently been referred to as the pylorus-preserving pancreatectomy. By 1986, Itani *et al.*[7] had collected details of 252 patients having this operation and concluded that the functional results were better with pylorus preservation than following the standard Whipple procedure where a portion of the stomach is removed. Warshaw and Torchiana[8] have highlighted problems with delayed gastric emptying and this delay occurred in 76 of the 252 patients collected by Itani[7]. Although the delay was usually transient, it persisted in a proportion of patients.

In assessing long-term function, preservation of the antropyloric segment appears to protect the patient from some of the nutritional and functional disabilities observed in those having the Whipple procedure. However, not all patients have experienced an entirely satisfactory course after pylorus-preserving pancreatectomy and it is not clear whether the late functional results were related to the initial delayed gastric emptying and apparent gastric malfunction.

Since 1980, 16 patients on the Gastrointestinal Surgical Unit at the St. George Hospital have had a pylorus-preserving pancreatectomy. This paper reports a prospective study of the functional results 3 months after operation and correlates them with the early recovery of gastric function.

Patients and methods

Clinical details of the 16 patients are summarized in *Table 1* The median age of the patients was 59·5 years (range 31–73). In nine patients, the indication for operation was periampullary carcinoma and all tumours were less than 3 cm in diameter; two patients had benign tumours causing common duct obstruction, five patients had resection for chronic pancreatitis. In 11 patients, only the head of the pancreas was resected. Total pancreatectomy was performed in five patients; three having had a tumour in combination with pre-existing diabetes and two patients having had chronic pancreatitis with small ducts and unremitting pain

At operation, the second, third and fourth parts of the duodenum were mobilized and resectability confirmed. The neurovascular attachments to the antrum and pylorus along the lesser curve and via the right gastric artery were carefully preserved. The gastroduodenal artery was divided close to its origin and this artery together with its associated lymph nodes and pancreaticoduodenal branches were removed with the specimen Continuity of the right gastroepiploic artery was therefore interrupted but the gastroepiploic arcade was preserved along the greater curvature. The duodenal bulb was transected 3 cm beyond the pylorus and, after completing the resection, the proximal jejunum was brought through a hole in the mesocolon and the divided first part of duodenum was anastomosed, end-to-side, to the jejunal loop, using

Table 1 *Clinical details for 16 patients having pylorus-preserving pancreatectomy*

a circular stapler. The common hepatic duct was anastomosed, end-to-side, to the jejunal loop, using 5/0 Ti-cron® (Cyanamid of Great Britain Ltd , UK). In the early part of the study, those patients having partial pancreatic resection had the body of pancreas anastomosed end-to-side to jejunum but in the last four patients the divided end of the pancreas was implanted into the back of the stomach.

Postoperatively, all patients had nasogastric suction using a sump tube. The jejunal loop was decompressed by a stent introduced through its blind end and passed down the lumen across the biliary anastomosis into the right hepatic duct

Recovery of gastric function was assessed in the early phase noting the duration of nasogastric suction, delay to successful introduction of a solid diet, and length of postoperative stay Postoperative complications were recorded. One patient died 10 days after her operation from a myocardial infarct, having made an otherwise satisfactory recovery. Non-fatal complications occurred in eight patients

Late gastrointestinal function was assessed 3 months after operation in 12 patients, the remaining four patients were excluded for the following reasons. early postoperative death ($n=1$); prolonged gastric stasis, necessitating further surgery ($n=2$); and persistent pancreatic sepsis and fistula ($n=1$).

Late function was assessed by ability to regain weight after operation, frequency of bowel motions and the requirement for pancreatic supplements. Absorption was measured by 3-day faecal fat estimations on a 'normal home diet', and gastric emptying of a standard mixed meal was measured by a dual isotope technique. Normal liquid emptying is exponential with 50 per cent emptying occurring between 15 and 20 min after ingestion; normal solid emptying is linear at 0 8–1 0 per cent clearance per min Validation studies for this test have shown that 95 per cent of normal subjects empty within these two ranges and rates outside these limits are considered abnormal Late complications were noted.

Results

Early function

In considering early gastric function (*Table 2*), the patients fall clearly into two groups. In the nine patients who had no abdominal complications other than gastric stasis after operation and in the patient who died subsequently from an infarct, the duration of nasogastric aspiration ranged from 4 to 25 days. Of these ten patients, seven had their nasogastric tube removed by the eighth day and another had it removed on the tenth day. Each of these progressed to a solid diet between 1 and 5 days later, with the latest commencing a solid diet on the 15th postoperative day and the earliest on the fifth postoperative day. Two patients without evidence of any other intra-abdominal complication had prolonged gastric stasis (18 and 25 days) with large volumes of gastric aspirate (>1000 ml/day). Both eventually required gastric bypass. At operation, the stomach was unremarkable and the duodenojejunal anastomosis appeared to be healing satisfactorily. In the first patient (No. 6), no mechanical reason for the delay was found Because he had had a previous Roux-en-Y choledochojejunostomy, the duodenojejunal anastomosis was technically more difficult and it was assumed that the additional mobilization of the pylorus and duodenum had denervated the sphincter. In the second patient requiring bypass (No. 14), the duodenum which had been anastomosed to the left aspect of the jejunal limb had rolled across towards the right causing torsion/angulation obstruction of the jejunum immediately distal to the duodenojejunal anastomosis. Local inflammatory reaction prevented simple correction of this rotation and the problem was corrected by jejunojejunal anastomosis. Although they both made a satisfactory recovery, the complication extended their hospital stay to 34 and 39 days respectively.

The second group contains those patients who developed other intra-abdominal complications (*Table 2*). In some, the nasogastric tube was successfully removed at an early stage but either had to be reinserted or there was significant delay in the introduction of a solid diet. In fact, the first indication of an intra-abdominal complication in some of these patients was food intolerance or gastric stasis. For those with uncomplicated postoperative recovery, the median length of stay was 14 days, with a range of 11–22 days. For the patients with intra-abdominal complications, the length of stay ranged from 27 to 183 days, with a median of 39 days.

Late function

All of the patients had lost weight before operation and many could not give an accurate estimate of their normal body weight. Of the 11 patients followed to 3 months, nine showed significant weight gain ranging from 2 to 10 kg. In three patients, the weight remained static.

Nine patients reported passage of normal stools once or twice each day. In the other three, bowel frequency was increased but only one of the three patients described steatorrhoea. At the time of writing, only four patients are regularly taking pancreatic supplements. However, the discovery of significant osteoporosis in the first patient, a man aged 53 at the time of his operation, has led to a more aggressive policy with the use of pancreatic supplements.

Faecal fat estimations performed on a normal home diet without pancreatic supplements in 12 patients gave a median faecal fat excretion of 12·9 g/day (range 1·8–42·1 g). Four of the patients (two having had total pancreatectomy) gave values within the normal range (less than 7 g fat/day). Four patients had faecal fat excretion of between 12 and 14 g per day and each reported passing normal stools with normal frequency and took no pancreatic supplements. Two of these four had had total pancreatectomy. Four patients had frank steatorrhoea and three of the four accepted advice to take pancreatic supplements.

Table 2 *Details of early postoperative function in 16 patients having pylorus-preserving pancreatectomy*

One refused to take the supplement, but gained weight and reported normal stool function after she was treated with an H_2-receptor antagonist.

Gastric emptying was measured at 3 months in nine patients in the latter part of the study. No consistent pattern emerged and there was no correlation between the delay to recovery of gastric emptying after operation and the rate of emptying measured 3 months later. This assessment is confused by the fact that postoperative complications appeared to be associated with early stasis in a number of these cases.

Late complications, probably related to the operation, have been observed in four patients. Three patients have developed endoscopically confirmed duodenojejunal ulceration presenting with bleeding; each required transfusion but did not require further surgery. Included in this number are the two patients who had prolonged early stasis necessitating a surgical procedure. In neither case had a vagotomy been performed. The third patient, 5 years after his operation, developed a jejunal ulcer which healed on H_2-receptor antagonist therapy. Also, he developed severe osteoporosis resulting in a compression fracture of T_{12}. In the fourth patient, a further laparotomy was required for small bowel obstruction.

Of the five patients who have died from recurrent carcinoma, none has shown evidence of involvement of the duodenal bulb to indicate compromised clearance. Each of these five patients had multiple liver metastases; in two cases these were heralded by unstable diabetes. In addition, three patients had retroperitoneal recurrence presenting with unremitting pain. Review of the histology in these three cases showed perineural or perilymphatic tumour involvement adjacent to the tumour yet only one of the three had positive lymph node involvement in the resected specimen.

Discussion

Our results show that it is not possible to make dogmatic predictions about the outcome in individual cases following pylorus-preserving pancreatectomy. In the early phase, most of the patients with delayed emptying also suffered an intra-abdominal complication In only two of the seven with significant early delay in emptying was there no extragastric cause. In the first of these two patients (No. 6), previous surgery for chronic pancreatitis had included a choledochojejunostomy for bile duct obstruction and it is possible that this interfered with the reconstruction. In the second patient, there was complete obstruction of the jejunum immediately distal to the duodenojejunal anastomosis apparently secondary to a form of torsion. A similar torsion effect has been observed by other surgeons (personal communication) but whether this is the cause of the gastric stasis or secondary to gastric dilatation is uncertain. Other authors[7,8,10,11] have reported a variable frequency for delayed emptying but it is not clear from most of these papers whether the delay occurred in patients making an uncomplicated recovery, or in those with significant complications. The time to removal of the nasogastric tube, commencement of early diet and length of postoperative stay in our uncomplicated patients is shorter than those reported by Warshaw and Torchiana[8], who have emphasized the frequency of early gastric stasis. Also, it is not clear from many of the discussions of the pylorus-preserving techniques whether or not the neurovascular supply to the pylorus was preserved. Cooper and Williamson[9] appear to be the only authors who have preserved the neural connections which run with the gastroduodenal artery to contribute to the plexus via the right gastroepiploic artery. They were not impressed with the benefits of this step in the four patients in whom it was used. We did not preserve the gastroduodenal artery, believing that in the patients with cancer, the trunk of the artery should be removed with the pancreas. However, in patients with benign disease, there is probably no reason why it could not be preserved.

In the early part of the study, where the standard pancreaticojejunal anastomosis employed for the Whipple reconstruction in our department over many years was attempted, there was an unexpected rate of leakage (*Table 2*). In the last four patients, where pancreaticogastrostomy was used, that problem has not been encountered.

The results in this series with regard to late gastrointestinal function are similar to those reported by Traverso and Longmire[10] and Newman *et al.*[11]. Of further interest is the similarity between the functional results observed in these patients where the second, third, and fourth parts of duodenum were resected and the results reported by Lambert *et al.*[12] for a new operation for chronic pancreatitis where the duodenum was carefully preserved.

Bowel function was reported to be normal by the majority of patients despite the frequency of biochemical steatorrhoea (*Table 3*). Only in those patients with grossly elevated levels of faecal fat was steatorrhoea recognized to be a problem by the patient. The frequency of steatorrhoea may be reduced in some patients by resorting to a low-fat diet rather than continuing with pancreatic supplements. In the longer term, this may not be a problem but the development of significant osteoporosis in a man, 5 years after pancreatectomy, is of concern. A careful analysis of his diet indicated a very low fat intake. A number of our patients admit that they have eliminated dairy products from their diet and that their meat intake consists of steamed or grilled fish or chicken. Our results for faecal fat estimation are very similar to those reported by Traverso and Longmire[10], but a similar range of values was reported after standard pancreaticoduodenectomy by Fish *et al.*[13]. The limited data available for patients having Whipple's procedure suggest a similar wide range of results but, since it is recognized that gastrectomy alone leads to a significant increase in the faecal fat levels[14], it is conceivable that the results will be less satisfactory. Although the numbers in the present series are small, there does not appear to be any gross difference in faecal fat excretion between those patients with a normal pancreatic tissue remnant and those with chronic pancreatitis. Of note is the satisfactory fat absorption, as judged by faecal fat estimation, in the four patients with total pancreatectomy (2·7, 5·3, 12·7 and 13·0 g/day). These patients, perhaps by virtue of their diabetic state, were much more conscious of their diet and regulated their fat intake.

Gastric emptying in our patients showed a range of differences from normal. However, there did not appear to be any obvious correlation with the clinical status of the patient. Patti *et al.*[15] showed similar variations when they examined ten patients some time after pylorus-preserving pancreatectomy. Of their ten patients, six were normal, three showed rapid emptying and one, delayed emptying. Although seven of their ten patients also showed rapid small bowel transit, most were asymptomatic. There was no difference in function between those with benign disease and those with carcinoma.

While the move from pancreaticojejunal anastomosis to pancreaticogastrostomy later in this study does not appear to have influenced the long-term results it is hoped that it may have overcome some of the technical difficulties. Undoubtedly, the anastomosis to the stomach is simpler than that to jejunum. Access to the body of pancreas is limited if a technique preserving all neurovascular attachments to the stomach is utilized. The technique of pancreaticogastrostomy was described by von Reding[16] and, in a study of pancreatic function after the standard Whipple procedure but employing a pancreaticogastrostomy, Christiansen *et al.*[17] suggested that pancreatic enzymes were not inactivated in the stomach and that there was no tendency towards stenosis of the pancreatic duct. The only complication we have observed from this procedure was haemorrhage from a small artery on the lateral margin of the pancreas, which was successfully controlled by endoscopic methods.

From this study, we conclude that the functional results are satisfactory after pylorus-preserving pancreatectomy and may be an improvement on those achieved with the Whipple pancreatectomy. The mechanism for the delayed gastric emptying reported in a number of series is unclear. However, in some patients it is a reflection of perigastric inflammation or sepsis. Measures of function other than those of gastric emptying, such as acid secretion and serum gastrin levels following pylorus-preserving pancreatectomy, have been studied[18] and, by those parameters, gastric function is essentially normal. One possible explanation for the delayed gastric emptying is the observation by Barkin *et al.*[19] that as many as 60 per cent of patients with pancreatic cancer have delayed gastric emptying preoperatively. In patients with advanced pancreatic cancer, that might be explained on the basis of perineural infiltration, but that should not be the explanation for the delay in those with benign disease or localized tumour.

C-reactive protein, antiproteases and complement factors as objective markers of severity in acute pancreatitis

C. Wilson, A. Heads, A. Shenkin and C. W. Imrie

Departments of Surgery, Immunology, and Pathological Biochemistry, Royal Infirmary, Glasgow, UK

Correspondence to:
Mr C. Wilson, Division of Surgery, Royal Infirmary, Glasgow G4 0SF, UK

In a series of patients with acute pancreatitis we have studied complement factors, antiproteases (α_2-macroglobulin and α_1-antiprotease) and C-reactive protein to determine the value of their sequential measurement in the prediction of outcome relative to clinical assessment and current multiple factor scoring systems. Complement factors were unhelpful in predicting the severity of an attack. α_2-Macroglobulin levels were significantly lower in complicated attacks during days 3–8 and α_1-antiprotease levels were significantly higher during days 4–8. C-reactive protein concentrations showed the best discrimination between mild and complicated attacks, levels rising higher and persisting for longer in complicated attacks; these differences were highly significant from day 2 (the morning after admission) to day 8. The concentrations providing the best discrimination were found to be $\geqslant 210$ mg/l for the peak C-reactive protein (on the second, third or fourth day) and $\geqslant 120$ mg/l for the C-reactive protein at the end of the first week. Analysis demonstrated both the peak or seventh-day C-reactive protein concentration to be of similar accuracy to either the Ranson or Glasgow multiple factor scoring systems and slightly better for attacks associated with gallstones. The C-reactive protein assay is simple, quick to perform, provides useful clinical information and is more likely to be of value and to be adopted into routine clinical practice than multiple factor scoring systems.

Keywords: Pancreatitis, outcome, C-reactive protein, antiproteases, complement

Edmondson and Berne in 1944 were first to suggest that measurement of a single biochemical factor, that of hypocalcaemia, might be a useful predictor of outcome in acute pancreatitis[1]. Laboratory prediction of severity in acute pancreatitis has become accepted since 1974 when Ranson *et al.*[2] described a scoring system utilizing 11 objective factors, each with significant prognostic value. Imrie *et al.*[3] in 1978 published a simplified system, modified for use in patients in the UK and based on nine factors. Multiple factor scoring systems reflect respiratory, renal, liver and haematological disturbance in the body and provide some clinically useful information but may be influenced by the patient's pre-admission state and the aetiology of the attack. The greater age of the patients and the early, transient liver dysfunction commonly associated with gallstone pancreatitis result in such patients consistently scoring higher than an alcohol-associated attack of equivalent severity. This has led to modifications being made to both major scoring systems; Ranson now describes two different scoring systems, one for gallstone and one for non-gallstone attacks[4] while the Glasgow scoring system, which has been simplified to include only eight factors[5], remains applicable to both common aetiologies of acute pancreatitis[6].

Multiple factor scoring systems have been widely used in the study of patients with acute pancreatitis, providing stratification of the risk of death or major morbidity and comparison of patients between different centres. Their complexity, however, probably limits their routine use in daily clinical practice. Neither system can be applied sequentially to monitor the course of the attack which might usefully assess the response to therapy or provide warning of a developing late complication.

Other possibly useful biochemical indicators of severity in acute pancreatitis include complement factors[7–10] and the antiproteases (α_2-macroglobulin and α_1-antiprotease)[10,11]. The value of C-reactive protein measurement in acute pancreatitis was first suggested by Mayer *et al.* in Leeds in 1984[12] and subsequently by others[10,13]. A comparative study examining the ability of multiple factor scoring systems and these individual biochemical parameters to predict outcome early in the course of the illness has not been reported, although a persistently high C-reactive protein concentration at the end of the first week appears to identify patients at risk of developing a late pancreatic collection[12].

We have undertaken a study of five complement factors, the two major antiproteases and the non-specific inflammatory marker C-reactive protein to determine the value of their sequential measurement in the prediction of outcome from acute pancreatitis relative to clinical assessment and the multiple factor scoring systems.

Patients and methods

Acute pancreatitis was initially diagnosed in all patients on the basis of a serum amylase >1200 units/l (normal range, 70–300 units/l) (Phadebas, Pharmacia Diagnostics AB, Uppsala, Sweden) and a compatible clinical picture[14]. Laboratory data were collected prospectively from all patients to permit scoring of both the Ranson and Glasgow multiple factor systems. As the aetiology of the attack was not usually apparent on admission, the original Ranson scoring system has been used throughout[2].

Blood samples were taken on the day of admission (day 1) and each morning thereafter until day 8 or until discharge if sooner. Samples were centrifuged and frozen within 60 min of venepuncture. Complement factors were measured on plasma samples stored at −60°C until analysis. C3 and C4 were measured by radial immunodiffusion (Behring Diagnostics, Hounslow, Middlesex, UK) and factor B by immunodiffusion using an in-house prepared agar plate containing antihuman properidin factor B (Atlantic Antibodies, Winnersh, Berkshire, UK). C1q and C3d were measured on a Beckman ICS nephelometer using antihuman C1q (Atlantic Antibodies) and antihuman C3d (Dako Ltd., High Wycombe, Buckinghamshire, UK) according to the method of Vergani[15]. Anti-

0007–1323/89/020177–05$03.00 © 1989 Butterworth & Co (Publishers) Ltd

proteases and C-reactive protein were measured on serum samples stored at −20°C before analysis. α_2-Macroglobulin and α_1-antiprotease were measured by turbidimetric immunoassay (Atlantic Antibodies). C-reactive protein was measured by a fluorescence polarization immunoassay (Abbott TDX, Abbott Laboratories Ltd, Wokingham, Berkshire, UK). Normal complement and acute phase protein ranges were established on 30 and 100 normal controls respectively

The patients studied fell into two groups: 30 patients had complement factors assayed and 72 patients had antiproteases and C-reactive protein assayed The first 50 patients who had antiproteases and C-reactive protein measured were studied consecutively; the remaining 22 were selected for study from the next 60 patients admitted, having been judged as having moderate or severe pancreatitis on the basis of a clinical assessment on admission. Clinical assessment was repeated at 24 and 48 h; those judged to have severe pancreatitis on assessment were considered at risk of death or of developing a complication.

Complicated attacks of acute pancreatitis were defined as resulting in death or a local pancreatic complication: abscess, pseudocyst or necrosis (defined as necrotic pancreatic and/or peripancreatic tissue recovered at laparotomy or post mortem). Nine additional patients manifested acute respiratory insufficiency defined as a $P_{O_2} < 60$ mmHg, requiring oxygen by mask for more than five consecutive days (mean, 8 days). Each had a prolonged, clinically severe illness with a mean hospital stay of 20 days, although ultrasound scanning in each failed to demonstrate local pancreatic complications. Nine (30 per cent) of the patients whose complement factors were measured had a complicated attack with two deaths (7 per cent) compared with 25 (35 per cent) and ten deaths (14 per cent) respectively for those having antiproteases and C-reactive protein measured.

Statistical analysis was performed using the Mann–Whitney *U* test.

Results

Complement factors C3 and factor B concentrations showed an early fall followed by a sustained rise during the course of the illness in both mild and complicated attacks, factor B rising above the normal range in both groups of patients. The individual results showed a wide scatter and no difference emerged between mild and complicated attacks. C4 concentrations showed no significant changes in either mild or complicated attacks through the course of the illness. C1q levels fell during the attack, falling below the normal range in complicated attacks, but these differences failed to reach statistical significance. C3d levels (a product of C3 activation) were increased in 33 per cent of patients at some time during their illness, thus indicating complement activation, but this could not be related to the severity of the attack judged clinically or on multiple factor scoring.

α_2-Macroglobulin levels fell during the attack, with levels significantly lower in complicated attacks between days 3 and 8 (*Figure 1*). α_1-Antiprotease levels rose during the attack in both mild and complicated attacks, with levels significantly higher in complicated attacks between days 4 and 8 (*Figure 2*).

C-reactive protein levels provided the best discrimination, with levels markedly higher and persisting for longer in those with complicated attacks, these differences were highly significant from day 2 (the morning after admission) to day 8 (*Figure 3*). C-reactive protein, therefore, was shown to be the best of all the factors tested for sequential monitoring of acute pancreatitis. Eight of the 11 patients subsequently developing pancreatic necrosis or pseudocyst had a peak C-reactive protein concentration of ≥300 mg/l. However, the mean C-reactive protein concentration did not distinguish these 11 patients (six of whom ultimately required surgery) from nine patients with acute respiratory insufficiency, all of whom had a severe illness but settled without surgery (*Figure 4*). C-reactive protein levels did not predict death in three elderly patients who died from shock on the second day of admission.

The C-reactive protein concentration providing the best discrimination (combining the highest sensitivity and specificity) was determined both for the peak C-reactive protein (occurring between the second and fourth day of illness) and for the concentration at the end of the first week. The best discrimination was found with a peak C-reactive protein concentration of ≥210 mg/l and, at the end of the first week, ≥120 mg/l (*Figures 5* and *6*). Applying these levels to the data permitted comparison of the prognostic value of C-reactive protein measurement with clinical assessment and the multiple factor scoring systems. *Table 1* shows both the peak and 7-day C-reactive protein concentrations to be of similar accuracy to either the Ranson or Glasgow multiple factor scoring systems.

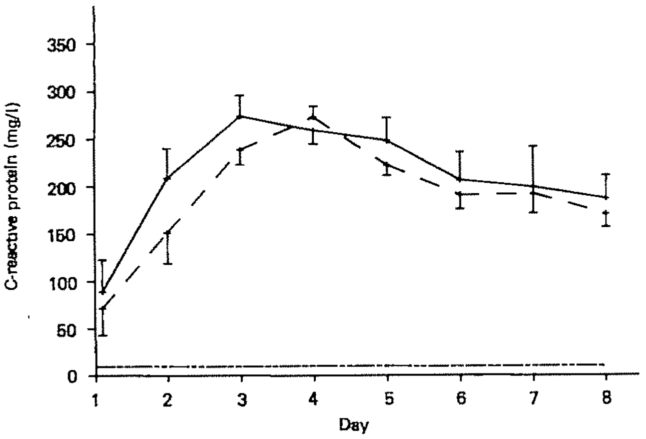

Figure 4 *Mean C-reactive protein concentrations in 11 patients with pancreatic necrosis or pseudocyst (——) and nine patients with acute respiratory insufficiency (– – –). -·-·-, Upper limit of normal for C-reactive protein*

Table 1 *Comparison of the peak and 7-day C-reactive protein concentrations with the Ranson and Glasgow multiple factor scoring systems*

	Sensitivity (%)	Specificity (%)	Correctly classified (%)
Peak C-reactive protein (≥210 mg/l)	83	85	85
C-reactive protein at 7 days (≥120 mg/l)	90	85	87
Glasgow score (8 factors)	76	83	81
Ranson score (11 factors)	88	79	82
Clinical assessment (on admission)	38	96	76
Clinical assessment (at 48 h)	46	98	80

Peak C-reactive protein, highest concentration on the second, third or fourth day; sensitivity, percentage of all complicated attacks predicted correctly by test; specificity, percentage of all mild attacks predicted correctly by test

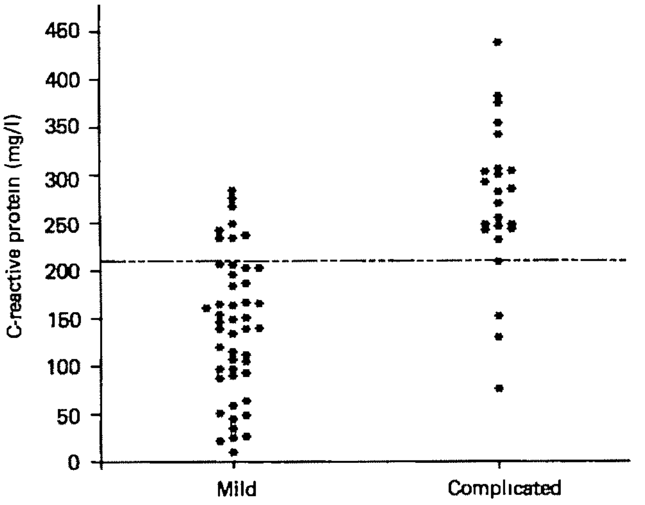

Figure 5 *Scattergram showing discrimination between mild and complicated attacks of pancreatitis based on the peak C-reactive protein concentration recorded on days 2–4. -·-·-, The peak concentration providing the best discrimination was ≥210 mg/l*

Table 2 *Comparison of C-reactive protein and multiple factor scoring systems in gallstone and alcohol-associated attacks*

Parameter	Sensitivity (%)	Specificity (%)	Correctly classified (%)
Gallstone			
Peak C-reactive protein (≥210 mg/l)	100	79	88
C-reactive protein at 7 days (≥120 mg/l)	100	100	100
Glasgow score	80	71	75
Ranson score	90	71	79
Alcohol			
Peak C-reactive protein (≥210 mg/l)	100	87	90
C-reactive protein at 7 days (≥120 mg/l)	67	86	82
Glasgow score	67	100	93
Ranson score	83	96	93

Peak C-reactive protein, highest concentration on the second, third and fourth day; sensitivity, percentage of all complicated attacks predicted correctly by test; specificity, percentage of all mild attacks predicted correctly by test

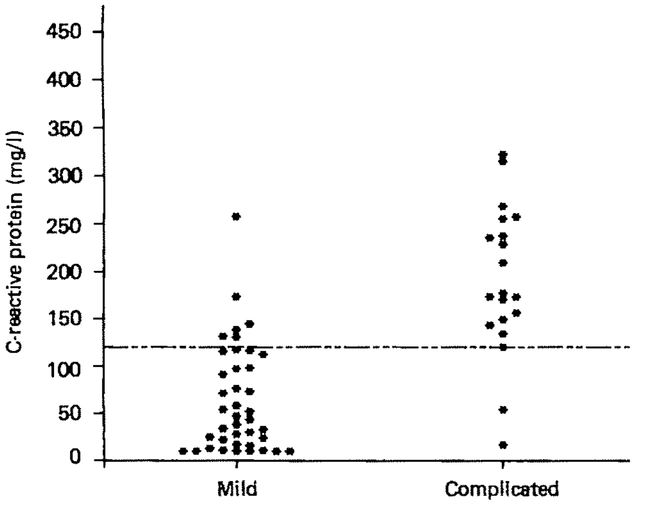

Figure 6 *Scattergram showing discrimination between mild and complicated attacks of pancreatitis based on the C-reactive protein concentration on day 7. -·-·-, The peak concentration providing the best discrimination was ≥120 mq/l*

When the aetiology of the attack was considered, C-reactive protein measurement appeared to be slightly better than either multiple factor scoring system for attacks associated with gallstones but slightly less good for alcohol-associated attacks (*Table 2*).

Although the proportion of attacks correctly predicted by clinical assessment approached that of the multiple factor scoring systems, closer examination revealed that while almost all mild attacks were identified correctly, fewer than half the patients with complicated attacks were correctly identified at 48 h.

Discussion

Clinical assessment of the severity and likely outcome of acute pancreatitis early in the course of an attack is notoriously unreliable. The accuracy of clinical assessment appears to improve with time and one study suggested that 83 per cent of severe attacks were correctly predicted 48 h after admission[16]. Our own data have demonstrated that while all patients subsequently dying were correctly identified as having a severe attack at 48 h, the overall accuracy in predicting complicated attacks was poor at 46 per cent. Clinical assessment, although an essential component of the overall monitoring and treatment of such patients, remains imprecise, subjective and non-reproducible, and the search continues for an ideal objective marker of severity in this condition.

Complement factors showed no relationship to the severity of an attack and their measurement was therefore discontinued after 30 patients had been analysed. Other workers have found complement levels, particularly C3 levels to be of value in the prediction of outcome in acute pancreatitis[7-10]. Whicher *et al.*[17] found, as we did, a wide scatter of results and no apparent relationship between the presence or absence of complement activation (as indicated by an increased C3d) and severity of the attack. The most promising of the complement factors studied was C1q. This is the first component of the classical complement pathway and its apparent consumption in acute pancreatitis is difficult to explain. Complement activation in acute pancreatitis is thought to occur by a direct attack on C3 by trypsin[18] or, as Foulis and co-workers have suggested, by the alternative complement pathway[8]. Neither should lead to consumption of the early factors of the classical complement pathway. C-reactive protein binds at sites of injury within the body and once complexed is a potent activator of the classical complement pathway, beginning with C1q[19] The fall in C1q which occurs in the more severe cases may therefore be associated with this mechanism.

Sequential measurement of the antiproteases appeared more promising, particularly α_2-macroglobulin which showed useful discrimination between mild and complicated attacks. α_2-Macroglobulin is most probably the key intravascular antiprotease. It binds irreversibly with activated proteolytic enzymes leading to a conformational change within the antiprotease molecule and its rapid uptake by the macrophages of the reticuloendothelial system. α_2-Macroglobulin does not act as an acute phase reactant since its synthesis does not increase in response to injury. The low levels of α_2-macroglobulin seen in the most severe attacks of acute pancreatitis suggest its consumption and may reflect the amount of proteolytic enzyme activation that is occurring. A proportion of the measured α_2-macroglobulin in serum in severe acute pancreatitis is in a complexed form and unavailable for protease binding[20]. The importance of low levels of this antiprotease is unclear but may have clinical relevance.

α_1-Antiprotease acts as an acute phase reactant, levels rising several-fold during the illness. The net effect is that the overall capacity of serum to bind trypsin and other activated proteolytic enzymes increases during the course of the attack[21]. The binding between α_1-antiprotease and trypsin is reversible and this complex appears to dissociate, the trypsin being taken up by α_2-macroglobulin before its clearance from the body[22]. Therefore, although the total trypsin binding capacity of serum may increase, the fall in α_2-macroglobulin may be a rate-limiting step to the clearance of proteases from the circulation. Clearance of α_2-macroglobulin–trypsin complexes by the reticuloendothelial system may also be depressed in severe acute pancreatitis[23] and, as these complexes retain proteolytic activity[24,25], this might be pathogenic in man. A recent controlled clinical trial has studied the therapeutic benefit of fresh frozen plasma in acute pancreatitis Infusion of fresh frozen plasma was able to restore α_2-macroglobulin levels in treated patients but produced no clear evidence of a beneficial effect, although too few patients with severe illness had been included to confirm this statistically[26].

In our experience the C-reactive protein concentration provided the best discrimination of all the factors investigated in the present study. C-reactive protein is a protein of uncertain role in the body. It acts as a non-specific inflammatory marker and monitoring has been shown to be of clinical value in a number of conditions[19]. C-reactive protein is usually present in low concentrations in the bloodstream It is synthesized in hepatocytes, elevated serum levels being detected about 8 h after injury and reaching a peak some 24–48 h later. The delay until peak levels are attained may account for the failure of C-reactive protein to detect the risk of early death in three patients in this study.

Beger's group has suggested, on the basis of a rather limited study of 35 patients, that a C-reactive protein concentration >100 mg/l correctly predicts pancreatic necrosis in 95 per cent of cases[10], these patients having necrosis confirmed at subsequent laparotomy. We cannot agree with this view as in our practice this level would result in 57 (79 per cent) of the 72 patients reported here having 'pancreatic necrosis' predicted. We have found that while a cut-off level of ≥210 mg/l (more than twice that described by Beger's group) identifies a group of patients with severe pancreatitis, it was clearly not specific for the presence of pancreatic necrosis. While a number of the patients in our severe group may have had unsuspected pancreatic necrosis manifesting only as acute respiratory insufficiency, the clinical improvement that occurred without recourse to surgery suggests that Beger's group has a lower threshold for surgery and may be operating unnecessarily in some patients.

The assay for C-reactive protein is simple and quick and we have demonstrated that measurement of C-reactive protein is at least as accurate as either of the multiple factor scoring systems and probably better for gallstone-associated attacks, which presently account for more than 50 per cent of patients in the UK. In practice, a peak C-reactive protein ≥300 mg/l and/or persistent elevation at the end of the first week, as was originally shown by the Leeds group[12], provide useful warning of the development of local pancreatic complications. Such a test would clearly be of clinical value in selecting patients for investigation by expensive imaging techniques, such as contrast-enhanced computed tomography; it would select those patients who might usefully be monitored in an intensive care unit, or those in whom parenteral nutrition may be indicated if the attack appears to be slow in settling. The complexity of multiple factor scoring systems has probably limited their routine use and measurement of a single factor, such as C-reactive protein, appears more likely to be adopted into daily clinical practice.

Characterization of breast cancer subgroups in an African population

A. A. Otu, I.-O. A. Ekanem*, M. I. Khalil*, M. D. Ekpo* and E. B. Attah*

*Departments of Surgery and *Pathology, College of Medical Sciences, University of Calabar, Calabar, Nigeria*

Correspondence to: Mr A. A. Otu

A detailed prospective study of 58 consecutive breast cancer patients and contemporaneous controls, using age, duration of tumour and presence or absence of poor prognostic signs as clinical parameters, clearly showed that the patients fell into three distinct groups. Group A accounted for 30 per cent of cancers and consisted of young women (21–45 years) with advanced cancers, a short history (3 months or less) and poor prognostic signs; these patients had fast-growing tumours. Group B, to which nearly 60 per cent of patients belonged, was made up of menopausal women (46–50 years) with advanced disease, a history of from 3 months to 1 year and poor prognostic signs; their tumour growth rate was intermediate. Group C made up slightly more than 10 per cent of cases and consisted of postmenopausal women (50 years and above) who gave a long history (1 year or more), and had resectable tumours without poor prognostic signs. Thus, although advanced breast cancer in tropical Africa is due to late presentation in the majority of cases, a small but significant proportion of women have advanced disease in spite of early presentation, attributable to fast tumour growth rate.

Keywords: Breast cancer, prognostic signs

In tropical African countries most breast cancer patients seek hospital treatment when the disease is far advanced; consequently little can be done and the prognosis is uniformly poor[1–3]. This contrasts markedly with reports of early resectable disease in western countries where tumours are increasingly being diagnosed by mammography and treated before they become clinically palpable[4,5]. Generally, African patients present late and the temptation has been strong to attribute the extensive breast cancers to late presentation. The present prospective study reviews consecutive patients seen at the University of Calabar Teaching Hospital in the 5-year period from January 1980 to December 1984 A detailed investigation of patients and contemporaneous controls with benign breast lesions was conducted using the clinical criteria of age, duration of tumour, presence or absence of those physical signs known to be associated with poor prognosis, and tumour resectability. The study has attempted to determine whether late presentation is solely responsible for advanced tumours and to provide preliminary data concerning breast cancer for further exploration. Clinical methods of investigating breast cancer are still very important and relevant in this region with comparatively low levels of technology and where sophisticated investigative tools are not available.

Patients and methods

The study was conducted in the 5-year period from January 1980 to December 1984 during which 259 consecutive patients with breast tumours attended the University of Calabar Teaching Hospital, Calabar A detailed clinical history with particular attention to the duration of the tumour was obtained from each patient, this was followed by physical examination with emphasis on those physical signs that are known to be associated with extensive disease and carry a poor prognosis, as described by Haagensen[6]

A plain X-ray of the chest was taken and, where indicated, a skeletal survey was conducted. Haemoglobin, total white cell count and differential were obtained. Age-matched female patients with benign breast lesions provided contemporaneous controls to women with breast cancers An excision or incision biopsy of each breast tumour was taken where applicable and paraffin sections stained with haematoxylin and eosin were examined histologically Further local treatment, where indicated, consisted of simple mastectomy with ipsilateral axillary node sampling. All patients were followed up until lost to follow-up or death, a period of 1–5 years.

Results

Incidence of breast cancer

Of the 259 patients seen, 69 (26·6 per cent) had malignant breast tumours and 190 (73·4 per cent) had benign tumours. Of the 69 malignant tumours, 67 (97 per cent) were breast cancer; two were Burkitt's tumour (African childhood lymphoma) in children aged 1 and 16 years.

Sex incidence

Nine of the 67 (13 per cent) breast cancer patients were male, giving a male:female ratio of 1 7. Features of the disease in the nine male patients are reported elsewhere.

Age incidence

Figure 1 shows the age distribution of the 58 women with breast cancer. The age ranged from 21 to 70 years with a mean of 40 years. The peak incidence is biphasic. an early peak occurs in the 26–35 years group and a late and even higher peak occurs in the 46–50 years group. Over half of the women were aged 40 years or less and 12 (21 per cent) were 30 years or younger.

Poor prognostic signs

Matted or ulcerated lymph nodes in the ipsilateral axilla were seen in 51 of 58 (88 per cent) cancer patients, ulcerated tumours in 41 (71 per cent) patients, and peau d'orange in 38 (66 per cent) Other poor prognostic signs included fixation of the cancer to the chest wall in 27 (47 per cent) patients and total breast involvement by tumour, lymphoedema of the upper extremity, and distant metastasis in 18 patients each.

Duration of tumour

Patients were categorized into three groups based on the duration of tumour: duration of tumour 3 months or less, duration of tumour from greater than 3 months to 1 year, and duration of tumour greater than 1 year. Seventeen (29 per cent), 33 (57 per cent) and eight (14 per cent) patients respectively belonged to the three groups.

0007–1323/89/020182–03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

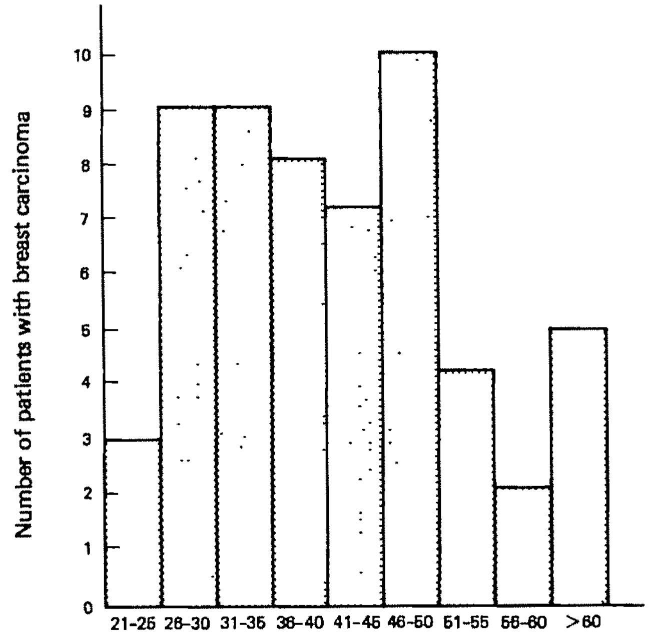

Figure 1 *Histogram showing age distribution of 57 of the 58 patients with breast cancer*

Table 1 *Histological types of breast carcinoma in 58 patients*

	No. of patients	Percentage
Infiltrating ductal	38	66
Medullary	8	14
Scirrhous	7	12
Scirrhous with medullary	2	3
Mucinous	3	5

Fertility and parity

Of the 58 patients, 56 (97 per cent) were multiparous: the other two patients were nulliparous. The number of children born ranged from two to ten with a mean of five. All the patients had successfully breast-fed their infants for periods ranging from 3 months to 2·5 years.

Histological types of cancer

The histological types of cancer are shown in *Table 1*, the commonest type of tumour was the infiltrating ductal tumour seen in 38 (66 per cent) patients. Associated intraduct carcinoma *in situ* was seen in five cases and lobular carcinoma *in situ* in one case.

Side and site

The right:left ratio was 4.3, thus giving a slight right to left preponderance. The commonest tumour site was the upper outer quadrant, seen in 17 of 58 patients.

Age at menarche and menopause

The mean age at menarche was 12·1 years in cancer patients and for non-cancer patients it was 12·0 years. The age at menopause was 42·1 years for cancer patients and 42·2 years for controls.

Tumour growth characteristics

By combining age, presence or absence of poor prognostic signs, and duration of symptoms, the patients could be allocated to three distinct groups (*Table 2*).

Group A (16 patients) were those who were aged 21–45 years, had a tumour duration of less than 3 months and in whom one or more poor prognostic signs were present at first presentation. These signs were present even though the tumours had been present for less than 3 months, so the rate of growth of tumour in these patients was fast. In contrast, seven patients in group C aged over 50 years with tumour duration of more than 1 year had no poor prognostic signs; the growth rate of tumour in this group of patients was slow. Between these two distinct groups was a third group of patients (group B: 33 patients) aged between 46 and 50 years with tumour duration of more than 3 months but less than 1 year and poor prognostic signs at first presentation; the growth rate of tumour in this group was intermediate.

Survival

Only eight of the 58 patients (14 per cent) were alive at 5 years; one belonged to group A and seven to group C. In contrast, 56 of the 58 (97 per cent) controls were alive at 5 years; two controls were lost to follow-up and were presumed dead.

Discussion

In this African population, breast cancer is predominantly a disease of young women compared with series from western countries. Two peaks of incidence are discernible; an early peak made up of young patients in the 26–35 years group and a late and even higher peak consisting of older patients in the 46–50 years group

The majority of women presented with advanced disease, these women had come to hospital as a last resort seeking treatment that could rid them of their malodorous ulcerated tumours and make them acceptable in their homes and community. This finding corroborates with those of previous reports[1,7].

Using the criteria of age, tumour duration[8] and the presence or absence of poor prognostic signs, patients were classified into three distinct groups. Two groups exhibited poor prognostic signs and their cancers were beyond surgical extirpation. In contrast patients in the third group were without poor prognostic signs and had improved survival.

The impression in this and other tropical African countries is that breast cancer patients present with advanced tumours because they report to hospital late[2,6,7] This was true of group B patients who constituted nearly 60 per cent of patients in the present study. However, there was a distinct group of patients who at first presentation showed extensive disease in spite of a short history; these patients belonged to group A and accounted for approximately 30 per cent of breast cancer cases.

To improve the outlook for patients with breast cancer in tropical Africa, as in the West, earlier presentation is required In

Table 2 *Patient classification of tumour growth rate*

Group	No. of patients	Growth pattern
A	16 (29)	Age 21–45 years Tumour duration less than 3 months Poor prognostic signs present Fast tumour growth
B	33 (59)	Age 46–50 years Tumour duration from 3 months to 1 year Poor prognostic signs present Intermediate tumour growth
C	7 (12)	Age over 50 years Tumour duration over 1 year Poor prognostic signs absent Slow tumour growth

Percentages are given in parentheses

western countries current policy is aimed at reducing breast cancer mortality through population screening concentrated on the 50–64-year-old group by single-view mammography[5,9] as recommended by the World Health Organization[10]. However, African countries have inadequate medical facilities and low levels of technological development; they are unlikely to be able to afford mass screening. Measures aimed at early detection and prompt treatment of breast cancer in this region are urgently required and will require increased awareness of the disease in the population at risk. The findings of this study suggest that health promotion exercises should be aimed at women aged over 40 years in the first instance.

Residual tumour after biopsy for non-palpable ductal carcinoma in situ of the breast

Th. Wobbes,
J. G. M. Tinnemans* and
R. F. van der Sluis

Dr Th. Wobbes, Department of General Surgery, University Hospital, Nijmegen, PO Box 9101, 6500HB Nijmegen, The Netherlands

In a group of 40 patients with non-palpable ductal carcinoma in situ *(DCIS) of the breast, 41 breast specimens were available for studying residual tumour after biopsy. In one group of ten patients seen before 1977, simple histological examination revealed a 9 per cent incidence of residual tumour. However, after thorough examination residual foci of DCIS were found in 77 per cent of a subsequent group of 30 patients. This means that the majority of patients would have had to undergo reoperation if a breast-saving procedure had been performed. This fact must be taken into account when planning treatment of patients with non-palpable DCIS.*

Keywords: Ductal carcinoma *in situ*, breast cancer, residual tumour

Ductal carcinoma *in situ* (DCIS) or non-invasive ductal carcinoma of the breast is a challenging problem to the surgeon. There is continuing discussion in the literature regarding how to cope with this type of lesion. After biopsy alone 30–40 per cent of the patients may develop an invasive carcinoma[1–4]. With the increasing use of mammography in the detection of breast cancer, the surgeon is confronted more and more with lesions such as microcalcifications, which may be the only sign of DCIS[5]. Now that breast-conserving surgery is finding general acceptance in the treatment of invasive carcinoma it is necessary to evaluate some results in patients with DCIS in the light of this therapy.

We have analysed the data of patients with a non-papable form of DCIS in order to throw light on the problem of residual tumour after biopsy.

Patients and methods

The present study comprised 40 women aged 35–69 years, with a mean age of 53 years, treated in the period 1971–87 The breast lesion was non-palpable and detected by mammography, either in patients drawn from a population screening project (20 cases) or in patients who were examined because of symptoms (17 cases) or in patients who were followed after mastectomy (three cases). The latter three patients were treated 1–7 years earlier because of an invasive carcinoma or DCIS of the contralateral breast; one patient had synchronous bilateral non-palpable DCIS.

Until 1977 the non-papable lesions detected in ten patients (11 breasts) were dealt with by blind biopsy. Since that time preoperative needle localization was used with a self-retaining barbed guide wire[6].

After biopsy, specimen radiography was obtained in all cases. Basically, the biopsy procedure aimed to remove all of the clustered microcalcifications Because in cases of DCIS treatment consisted of an ablative form of surgery, the specimen was investigated only for diagnosis and no margins were studied. In 12 patients a simple mastectomy (one patient bilaterally) and in 28 patients a modified radical mastectomy was performed.

Thus 41 mastectomy specimens were available for study. In 30 cases Egan's method, correlating clinical, radiographic and pathological findings was used[7]. The breast was chilled overnight in a refrigerator at 2°C and sectioned microscopically at 5-mm intervals. Then a radiogram was made of the specimens. Radiologically suspected lesions were investigated histologically. In total, 15–20 blocks were obtained

In the other 11 cases dealt with in the period up to 1977, multiple biopsy samples were taken from all the quadrants of the removed breast.

Results

In all patients except one, mammography was carried out. Clustered microcalcifications were the only findings in 35 breasts. In four, a circumscribed mass with microcalcifications was found. In only one patient was a circumscribed mass without microcalcifications seen on the mammogram.

Residual tumour after biopsy was found in 24 of the 41 breast specimens (59 per cent). Residual tumour adjacent to the biopsy area was noted in only one of the ten patients (11 breast specimens, 9 per cent) who underwent a blind biopsy before 1977. In these patients radiological findings were not correlated with pathological findings.

In 23 of the 30 breast specimens (77 per cent) in which the lesion was localized preoperatively and where Egan's method of serial whole organ sectioning was used for investigation, residual foci of tumour were detected. In 11 of the 23 patients in this group the residual tumour was located adjacent to the biopsy area (48 per cent). In four patients, foci of DCIS were found in the quadrant in which the microcalcifications were located; in eight cases the tumour extended into two quadrants of the breast.

In 19 cases a comedo type of DCIS was found and in 22 a combination of papillary, cribriform and comedo type. There were no obvious differences in histological type between the groups with and without residual tumour.

Two patients had to be treated for invasive carcinoma of the contralateral breast after an interval of 16 and 19 months respectively. In none of the 28 patients who underwent a radical or a modified radical mastectomy were axillary lymph node metastases found. In the 12 patients treated by simple mastectomy, no regional recurrence was observed in a follow-up period ranging from 8 to 16 years.

Discussion

Non-palpable DCIS is probably an important precursor of invasive carcinoma. The only method to detect these non-palpable lesions is mammography, which finds more and more acceptance as a valuable tool in detecting mammary carcinoma at an early stage of disease. Clustered microcalcifications are a strong indicator of DCIS and every surgeon charged with the care of breast cancer patients will proceed to biopsy in such patients. However, these microcalcifications in DCIS are usually only part of a tumour which may be more extensive and not visible mammographically. In our series DCIS was left behind in almost 60 per cent of the patients after excision of the microcalcifications.

An important issue is the method used by the pathologist to establish the extent of the foci of tumours. When the breast specimens were studied according to Egan's method[7], residual tumour was found in 77 per cent of the cases, while in the breasts

0007–1323/89/020185–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

studied by random sampling from all quadrants, foci of DCIS were detected in only 9 per cent of cases. Possibly the preoperative localization procedure has contributed to this high percentage of residual disease, because the specimen subsequently taken at biopsy may be smaller and more directed to the microcalcifications than that removed by 'blind' biopsy.

In the literature the incidence of development of invasive carcinoma after local excision of DCIS (palpable and non-palpable) varies from 28 to 67 per cent and such invasive growth is caused by outgrowth of residual tumour[3,8,9]. At present it is questionable whether radiotherapy can reduce the risk of development of an invasive carcinoma from DCIS. The argument against radiotherapy is supported by Schnitt and coworkers in 1984 who found in a series of 154 patients with invasive carcinoma and breast-saving treatment that the local recurrence rate was significantly increased when invasive cancer was found in combination with DCIS[10]. Moreover, interpretation of a mammogram is easier in a non-irradiated breast than in a breast that has become fibrotic following radiotherapy. It is conceivable that detection of recurrence may be delayed in such irradiated breasts.

We have to realize that in non-palpable DCIS we have the opportunity to cure the patient by mastectomy. If the opportunity to carry out mastectomy is missed, is follow-up able to detect a small invasive carcinoma at an early enough stage that the patient can still be treated curatively? The only method of detecting such early recurrence is mammography, and it is questionable whether the tumour will present again with microcalcifications. The question of whether it is justified to excise the lesion and wait will have to be answered in time as a growing number of patients are treated by breast-conserving surgery[11].

If breast-conserving therapy is contemplated, all non-invasive tumour should be excised in order to minimize the risk of malignant transformation into invasive tumour. In that event the patient has to be operated on a second time, firstly because the biopsy procedure is not able to excise all tumour and secondly because it is not justified to make the diagnosis of DCIS solely on the basis of frozen section examination[12]. It is also important to determine whether all the microcalcifications are located in the biopsy specimen and to define where other foci might be expected. Exact documentaton of the orientation of the specimen in relation to the surrounding breast tissue is necessary to obtain an accurate impression of the extent of the lesion.

Theoretically, our data suggest that wide excision or quadrantectomy would be sufficient to remove all *in situ* lesions in some three-quarters of the patients. The problem is that one is never sure of having removed the affected segment, especially in patients with multicentric DCIS. In patients with a palpable tumour the surgeon may have some landmarks, but in a non-palpable lesion one cannot be certain that the mammographically detected lesions are located in the centre of the specimen. Thorough histological examination may indicate whether more foci of DCIS are to be expected in the surrounding breast tissue and in what direction the re-excision has to be done. If one pursues histological clearance of tumour this procedure is necessary and is a factor that must be taken into consideration before any trials are commenced.

Follow-up after treatment of primary breast cancer

This study evaluates the usefulness of routine follow-up of breast cancer patients. In all, 416 patients who were treated with curative intent for breast cancer were followed according to a fixed follow-up schedule for a minimum of 2·5 years and a maximum of 13·5 years (mean about 5 years). During the 4533 routine out-patient visits, 4116 chest radiographs, 3889 pelvic radiographs and about 17 000 laboratory tests were carried out routinely. In the follow-up period, 148 patients were found to have distant recurrence of whom 34 (23 per cent) had asymptomatic metastases and 114 symptomatic metastases. Of the 8005 routinely performed radiographs, 24 (0·3 per cent) revealed asymptomatic metastases, and the 17 000 laboratory tests led to the discovery of six asymptomatic bone and four asymptomatic liver recurrences. Screening for metastases did not result in a reduction of the lead time to the diagnosis of asymptomatic metastases; the disease-free interval was equal in both symptomatic and asymptomatic patients. Of the 46 locoregional recurrences 42 were found by physical examination during a routine follow-up visit and 37 had not been noticed by the patient. Seventeen second primary breast cancers were diagnosed, six of which were in stage I (<2 cm). Mammography was not a part of the routine follow-up scheme. It is concluded that routine follow-up of breast cancer patients by history and physical examination is sufficient to detect local recurrence and a second primary tumour as well as giving the opportunity to track signs and symptoms of distant recurrence at an early stage. Performing annual or biannual mammography is advisable, but the use of other costly routine investigations in the follow-up is not justifiable, as no therapeutic advantages can be expected.

After treatment with curative intent of a primary breast cancer many patients are followed by regular out-patient visits, consisting of physical examination, routine laboratory testing and routine radiological and radionuclide examination. The main objectives of such follow-up are to detect as early as possible locoregional as well as distant recurrence or a second primary in the other breast. The investigations used in the routine follow-up of breast cancer patients are: radiograph of the chest, bone-scan, liver function tests and carcinoembryonic antigen[1]. However, although there has been considerable discussion about the usefulness of these tests in detecting breast cancer recurrence[2–7], there has been little discussion about the yield of the investigations in the follow-up of breast cancer. Are these routine investigations able to detect an asymptomatic—early—recurrence in a significant percentage of patients and how great is the number of investigations needed to obtain this result? The main question is whether the detection of an asymptomatic recurrence is beneficial to the patient.

An analysis of data obtained from a fixed follow-up schedule, consisting of routine chest and pelvic radiographs and laboratory tests, carried out for 416 patients over a period of 13 years, has been made in an attempt to answer these questions.

Patients and methods

The present study includes all patients treated with curative intent for breast cancer from 1970 to 1981 in the St. Joseph Hospital in Eindhoven In 467 patients breast cancer was diagnosed, 33 patients had distant metastasis at first diagnosis (stage IV) and 18 were lost from follow-up or insufficient data were available The remaining 416 patients were mainly treated by radical (before mid-1976) or modified radical (after mid-1976) mastectomy with radiotherapy when indicated After treatment patients were seen in the out-patient clinic every 3 months in the first 2 years, every 6 months up to 5 years, and annually thereafter. Besides physical examination and history, a radiograph of the chest and pelvis was made routinely at each visit and alkaline phosphatase γ-glutamyl transpeptidase, calcium, erythrocyte sedimentation rate and carcinoembryonic antigen (after 1978) were checked. Bone-scanning, liver imaging or mammography were performed only when indicated

Patients were followed for periods of up to 13·5 years. The cumulative follow-up period was 23 500 months, an average of 56 months per patient, most follow-up examinations and controls were carried out by surgeons Of the patients 89 per cent were followed according to the schedule. A specially designed follow-up form was used for the documentation of the results of history, physical examination and routine investigations at each follow-up visit.

The end points of the registration of follow-up data were. the last follow-up visit, the diagnosis of distant recurrence, or death unrelated to breast cancer

After the detection of distant recurrence, the time to the last follow-up visit and the time to death were registered.

The number of visits and routine investigations are listed in *Table 1* The treatment of distant recurrence was diverse and depended on localization and spread of the disease, the menopausal status of the patient and the oestrogen-receptor content of the tumour.

The most important treatment modalities were radiotherapy, chemotherapy, ovariectomy, tamoxifen or oestrogens (ethinylestradiol).

Results

Distant recurrence was found in 148 patients (36 per cent) and locoregional recurrence in 46 (11 per cent). Seventeen patients (4 per cent) developed a second primary cancer in the other breast.

The sites of the distant recurrences are listed in *Table 2* At the time of first diagnosis of distant recurrence 114 patients had related symptoms and, because of these symptoms, 77 patients

© 1989 Butterworth & Co (Publishers) Ltd

had visited the out-patient clinic before the next scheduled visit. In other words, 34 patients had asymptomatic metastases which were discovered by routine investigation *Table 3* shows the means of discovery and the sites of these asymptomatic metastases.

At first diagnosis, 48 per cent of symptomatic patients had metastases at more than one site, against 21 per cent of asymptomatic patients (χ^2 test, $P<0\cdot05$) Survival after first diagnosis of distant recurrence was significantly longer for asymptomatic patients (see *Figure 1*). Of symptomatic patients, 70 per cent had axillary metastases at the time of primary treatment as against 53 per cent of the asymptomatic patients (χ^2 test, $P<0\cdot05$). *Figure 2* shows that the disease-free interval is the same for both asymptomatic and symptomatic patients.

Nine patients had their first detected metastases only in the lung, six of which initially seemed to be solitary. Five patients had progressive disease within 5 months. In one patient a wait-and-see policy was advised because of the lack of symptoms: 2·5 years later she died of the sequelae of progressive local tumour growth. Judged retrospectively, this patient might have benefited from a metastasectomy. None of the six patients with liver metastases as the only initial recurrence was considered to have solitary metastasis, neither were they regarded, retrospectively, to be resectable.

A locoregional recurrence was found during the follow-up period in 46 patients (11 per cent); in 42 patients this recurrence was found during a scheduled visit and 37 patients had not previously noticed this recurrence.

Seventeen patients developed a carcinoma in the other breast. Despite the regular physical examination only six second tumours were discovered at an early stage (<2 cm). The chance of finding a second primary breast cancer in this series is about 8·7 per 1000 follow-up years (17 in a total of 1958 years). The age-specific incidence of breast cancer in women over 30 years old in the Netherlands is 204 per 100 000 women per year (2·04 per 1000) The expected number of second breast cancers in a cumulative follow-up period of 1000 years is 2·04. The observed number of second breast cancers is 8·7; the observed.expected ratio is 4·2. Therefore in our population there is a fourfold increase in the risk of developing a second primary breast cancer.

Table 1 *The number of out-patient visits and routine investigations in 416 patients over a follow-up period of 13·5 years*

Investigation	*n*
Total out-patient visits	4533
Radiograph of the chest	4116
Radiograph of the pelvis	3889
Erythrocyte sedimentation rate	4153
Alkaline phosphatase	4101
γ-Glutamyl transpeptidase	3552
Calcium	3602
Carcinoembryonic antigen (after 1978)	1506

Table 2 *Site of distant recurrence at first diagnosis in 148 patients*

Site of recurrence	Only affected site	In combination with other sites	Total
Bone	51 (34)	41 (28)	92 (62)
Lung	9 (6)	29 (20)	38 (26)
Liver	6 (4)	26 (18)	32 (22)
Pleura	8 (5)	18 (12)	26 (18)

Lung/ovary*	1	—	—	—	1
Local/ovary*	—	—	—	—	1
Total	15	5	4	9	34

* After the detection of the asymptomatic lung and local recurrence these two patients underwent an ovariectomy In the ovaries of both patients an unexpected metastatic tumour was found. † This patient had asymptomatic distant recurrence in the ovary which was not discovered by routine investigations but which was discovered in the therapeutically removed ovary

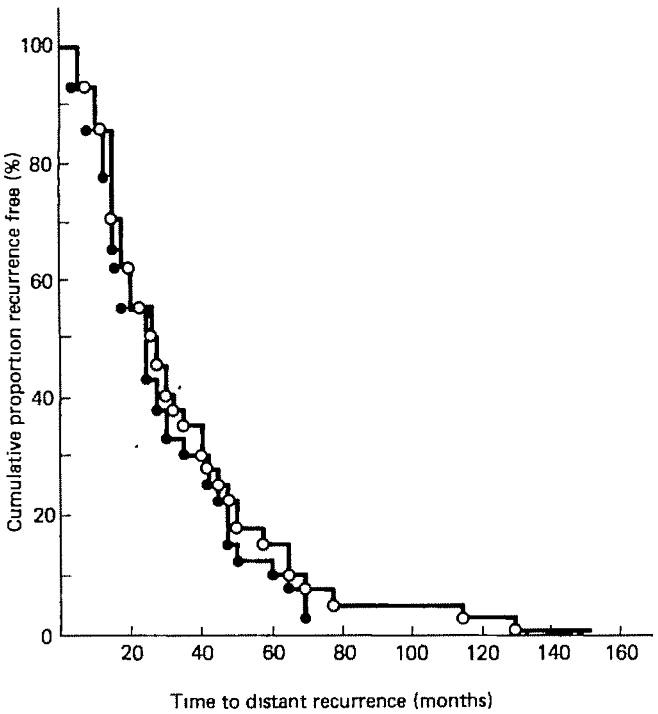

Figure 2 *Distant recurrence-free interval according to recurrence-related symptoms. Screening for metastases did not reduce the lead time in the diagnosis of asymptomatic metastases for there is no difference in the time to distant recurrence between 114 symptomatic* (○) *and 34 asymptomatic* (●) *patients* (*Lee–Desu statistic*[18])

Discussion

In order to detect a relatively small number of asymptomatic metastases (23 per cent of the total), it was necessary to carry out a large number of routine investigations: 4116 chest radiographs to discover 19 pulmonary, pleural or bone metastases; 3889 pelvic radiographs to discover nine bone metastases and about 17000 laboratory tests to detect six bone and four liver recurrences. This degree of investment is only justifiable if the patients can expect to benefit from the early detection of asymptomatic and distant recurrence.

What are, in theory, the most important benefits to be expected from early detection?

Firstly, a smaller tumour burden might give a better response to systemic therapy with a longer survival and/or symptom-free interval. Secondly, routine testing might provide an opportunity to detect solitary liver or pulmonary metastases at a stage when they can be cured by surgical excision.

However, one can raise several objections against these hypothetical advantages. The asymptomatic recurrence, as well as the symptomatic recurrence, represents a macroscopic tumour mass Both contain more than 10^{10} tumour cells. According to the theory of Goldie and Coldman[8] and Goldie[9], these tumour masses are supposed to contain a sufficiently large number of resistant tumour cells to ensure persistence of the tumour localization after endocrine therapy or chemotherapy In other words, in macroscopic metastatic breast cancer cure is not to be expected. In addition, as the difference between the number of resistant cells in asymptomatic or in symptomatic patients is small, no important survival benefit is to be expected by treating asymptomatic breast cancer metastases. There are some reports supporting this last statement: Zwaveling *et al.*[10], Brøyn and Frøyen[11], as well as Hietanen[12], were not able to detect any survival benefit from treating asymptomatic metastases. We did find a longer survival after detection of metastases in asymptomatic patients, but it was probably not due to better treatment response in the asymptomatic patients but to patient selection: most symptomatic patients had more extensive disease at the time of diagnosis of the recurrence and there had been a higher incidence of axillary metastasis in the symptomatic patients at the time of primary treatment. From these data one can speculate that patients whose recurrences presented with symptoms were suffering from a more vigorous type of breast cancer. In general, it is disputable whether systemic chemotherapy improves survival in metastatic breast cancer patients to the degree that it outweighs the discomfort caused by the treatment[13–15].

The hypothetical advantage of prolonging the symptom-free interval by treating asymptomatic metastases has to be weighed against the real disadvantage of shortening the subjective disease-free interval by detecting and treating asymptomatic recurrences The patient feels well but has been made aware of the fact that the disease has spread. Moreover she may receive a therapy which will make her sick. The treatment of metastatic breast cancer is nearly always palliative, with excellent results in only a small percentage of cases. Therefore, one should start this treatment only when clearly indicated

The chance of finding a curable, truly solitary, pulmonary or liver recurrence is extremely small. In our series there was probably an indication for a resection of a lung metastasis in only one patient and in none of the patients with liver metastases. Vincent *et al* [16] reported two patients, out of a group of 1000 patients with breast cancer metastases, who underwent a pulmonary metastasectomy resulting in a long survival

For this reason we feel that it is unnecessary to make an intensive and onerous search for asymptomatic breast cancer metastases. And thus, in our opinion, there is no need for routine biochemical and radiographic investigations in the follow-up of breast cancer patients. That regular physical examination is important has been shown by the fact that the great majority of local recurrences were detected during routine control visits Early detection and treatment of a local recurrence is able to prevent distressing local problems. As most distant recurrences are heralded by symptoms[17], it is important to see the patient regularly to give her the opportunity of bringing forward even minor complaints.

Because of the increased risk of a second primary tumour, surveillance of the other breast by regular physical examination and mammography is mandatory. There is a real chance for cure of a second primary breast cancer detected at an early stage. The optimal interval for mammography in this high-risk group of patients is not defined This interval will have to depend on supplementary risk factors, such as age, histological features of the primary tumour (lobular carcinoma) and family history. Probably, performing an annual mammography is a satisfactory compromise for most patients, although it is not clear whether such screening will improve survival for breast cancer treated patients.

In addition to these purely medical considerations, the regular routine check-up gives the patient the opportunity to present psychological problems, which are so frequent in breast cancer patients. The routine check-up is able to reassure the patient that 'all is well' and, last but not least, it gives the doctor the opportunity of evaluating the results of the breast cancer treatment as performed in the clinic.

In conclusion, follow-up after treatment for primary breast cancer is useful: local and/or regional recurrence, or a second primary breast cancer can be detected at an early stage. Signs and symptoms of possible distant recurrence will come to light and by further investigations any suspicion will be confirmed or excluded The only routine steps required are taking the history, physical examination, and an annual mammography, on a fixed time schedule. Carrying out other investigations is a costly way of detecting a few asymptomatic metastases for which no therapeutic advantages can be expected.

Prior renal transplantation does not facilitate subsequent canine islet allograft survival

Successful islet allografts can be established in rats bearing long surviving renal allografts, without additional immunosuppression, when kidney and islet donor animals are of the same strain. The applicability of such a scheme to clinical practice has been investigated in a large animal model of diabetes: the pancreatectomized dog. Eight dogs with previously established renal allografts and immunosuppressed with cyclosporin A received islet allografts from their respective original kidney donors. The median islet graft functional survival was only 10·5 days, significantly less than for six similarly immunosuppressed dogs receiving islet allografts alone (48·5 days, $P<0\cdot05$). Three of the sequentially transplanted dogs had had no renal graft rejection episodes before islet transplantation, yet their islet grafts were all rejected within 19 days. In the pancreatectomized dog, prior donor specific renal transplantation has an adverse effect upon subsequent islet graft survival.

Keywords: Diabetes, cyclosporin, islet transplantation, renal transplantation, immune tolerance

Prolonged islet allograft function has been difficult to achieve in most experimental models of diabetes mellitus when using conventional immunosuppression, but it must be demonstrated before safe clinical islet transplantation can proceed. Rats with established renal allografts, subsequently made diabetic with streptozotocin, regularly accepted islet grafts from the original kidney donor strain with prolonged reversal of diabetes and without the need for further immunosuppression[1]. These findings were independent of the strain combination and the site of islet graft placement[2]. If such a scheme were successful in a large animal model of diabetes it might have clinical application. Renal impairment or failure will develop in up to 40 per cent of insulin-dependent diabetic patients within 30 years of diagnosis[3] and many of these patients could be considered for renal transplantation. At the time of renal transplantation in a patient with diabetes, islets could be harvested from the same kidney donor and cryopreserved for transplantation once the renal graft was well established. Not only might the diabetic state be successfully reversed, but the transplanted kidney might be protected against the development of diabetic nephropathy[4]. The aim of this study was to investigate the feasibility of such a scheme using the pancreatectomized dog as a model of human insulin-dependent diabetes mellitus[5]. Islet graft survival after sequential renal and islet allotransplantation, with cyclosporin A immunosuppression, was compared with islet graft survival after similarly immunosuppressed islet allotransplantation alone

Materials and methods

Animals

Healthy young adult beagle dogs were used with weights ranging from 10·5 to 21·7 kg. They received a standard kennel diet supplemented with Pancrex Granule Fines (Paines and Byrne Ltd., UK) after pancreatectomy.

Experimental groups

Group 1: islet allograft ($n=6$)
Group 2: islet allograft + cyclosporin A ($n=6$)
Group 3: sequential renal then islet allograft + cyclosporin A ($n=16$)

All transplants were performed between unrelated animals (either from different colonies or unrelated for at least three or four generations according to breeders' records).

Animals in groups 1 and 2 underwent total pancreatectomy 1 week before islet allotransplantation, fasting normoglycaemia being maintained in the interim with subcutaneous insulin injections In group 3 renal transplants were established between 11½ and 15 weeks before islet transplantation from the original kidney donors. In group 3 recipients, pancreatectomy was performed at the same time as the islet transplant

Surgery

Animals were premedicated with atropine (300 μg) and acepromazine (1·5 mg). Anaesthesia was induced with thiopentone (10 mg kg^{-1}) and maintained with halothane, nitrous oxide and oxygen Cefuroxime (500 mg) was given at the start of surgery. Hartmann's solution, 100 ml h^{-1}, was given intravenously during surgery. Postoperative analgesia was ensured with buprenorphine (100 μg).

Total pancreatectomy was performed, preserving the pancreaticoduodenal vessels, and the excised gland was immediately placed in iced Hanks' balanced salt solution (HBSS)

For renal transplantation the left kidney was excised and flushed with iced heparinized kidney perfusion solution (Travenol, Thetford, UK). It was transplanted to the right iliac fossa of the bilaterally nephrectomized recipient animal and anastomosed end-to-end with the iliac artery and end-to-side with the iliac vein. An onlay ureteroneocystostomy was performed[6]. Fifty millilitres of 10 per cent mannitol solution was given intravenously during the anastomosis Kidney donor animals recovered from unilateral nephrectomy and subsequently acted as islet donors for their respective recipient animals.

Islet graft preparation and transplantation

Retrograde ductal perfusion (20 ml min^{-1}) of a 0·05 per cent collagenase solution (Sigma type X, activity 2400 units mg^{-1}) at 37°C for 18–24 min was followed by mechanical dissociation and serial sieving (425 μm pore size) in iced HBSS Graft fragments were separated by refrigerated centrifugation, final graft volume was measured and they were resuspended in iced HBSS with aprotinin (2×10^5 KIU litre^{-1}) for implantation. The presence of isolated islets in the graft was confirmed by immediate microscopy using a green filter[7]. Prepared islet grafts were implanted into the splenic pulp of recipient animals during temporary occlusion of the splenic vascular pedicle

Immunosuppression

Group 2 animals received cyclosporin A, 20 mg kg^{-1} day^{-1}, by intramuscular injection starting 5 days before islet transplantation After transplantation the dose was adjusted, attempting to maintain the plasma cyclosporin A concentration above 400 ng ml^{-1}. Cyclosporin A was given by intramuscular injection because of uncertainties about the adequacy of its gastrointestinal absorption after pancreatectomy, despite apparently adequate exocrine supplementation[8,9].

0007–1323/89/020191–04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Group 3 animals received cyclosporin A, 20 mg kg^{-1} day^{-1}, orally (the pancreas being entirely normal at this stage of the experiment), starting the day before renal transplantation. Following renal transplantation episodes of presumed renal rejection (diagnosed by a rapid rise in plasma creatinine concentration of $>35\,\mu$mol litre^{-1} day^{-1}) were treated with intravenous methylprednisolone, 60–120 mg, for 3 days. To ensure comparability with group 2, intramuscular cyclosporin A was started 5 days before sequential islet transplantation and oral cyclosporin A stopped 2 days beforehand Subsequent dose adjustment was as for group 2

Assessment

Fasting plasma glucose and insulin concentrations were measured after islet transplantation on days 1–14, 17, 21 and weekly thereafter. Plasma creatinine concentrations were measured on days 1–14 after renal transplantation and weekly thereafter. After the sequential islet transplant, creatinine was measured on the same days as glucose and insulin.

Plasma cyclosporin A concentrations were measured on days 0, 2, 4, 7, 10, 14 after islet transplantation and weekly thereafter and on the day of renal transplantation and then weekly Blood samples were incubated at 37°C for 30 min before plasma separation and analysis by polyclonal radioimmunoassay (Cyclosporin RIA-Kit, Sandoz Ltd , Leeds, UK).

Dogs ($n=16$) acting as kidney and islet donors for group 3 animals had their plasma creatinine concentrations measured before and after initial unilateral nephrectomy.

Criteria for experimental termination

The experiment was terminated if animals survived for 6 months after islet transplantation, if the fasting plasma glucose concentration was >25 mmol litre^{-1}, if animals lost more than 25 per cent of their preoperative body weight or if irreversible renal failure occurred.

Statistical analysis

Data are expressed as median and range The Mann–Whitney *U* test has been used for all comparisons

Results

In group 3, eight dogs died following initial renal transplantation: on day 7 (renal artery thrombosis), on days 6 and 8 (intussusception), and on days 36, 51, 51, 68, 70 (renal rejection with terminal creatinine concentrations of 627, 788, 666, 669, 867 μmol litre^{-1} respectively). Eight dogs survived to undergo sequential islet transplantation.

Islet graft function

There were no differences between the three groups in final pancreatic microfragment graft volume (or graft volume as a percentage of donor pancreas weight).

Days of islet graft function (maintenance of normoglycaemia) and the total number of days survived after islet transplantation in the three groups are shown in *Table 1*. Non-immunosuppressed allografts were rapidly rejected. Cyclosporin A immunosuppression allowed significant prolongation of islet allograft function (group 2 *versus* group 1, $P<0·005$). Sequential islet grafts functioned for a significantly shorter time than islet allografts (group 3 *versus* group 2, $P<0·05$) and animal survival was similarly reduced (group 3 *versus* group 2, $P=0·01$). Animal survival for group 3 was no different than for group 1.

(a), No episodes of previous renal allograft rejection, (b), multiple previous episodes of reversible renal rejection; (c), one episode of renal rejection

Cyclosporin A and creatinine

Plasma cyclosporin A and creatinine concentrations for groups 2 and 3 on the day of islet transplantation are compared in *Table 2*. There were no significant differences in cyclosporin A levels either then or during the subsequent post-islet transplant period. Group 3 animals had a higher median plasma creatinine concentration on the day of islet transplantation, although this did not reach statistical significance ($P=0·06$).

Individual group 3 results

The eight dogs in group 3 which received sequential islet grafts had marked differences in renal function and are considered in three subgroups. The terminal plasma glucose and creatinine concentrations for these animals are shown in *Table 3*.

No episodes of previous renal allograft rejection. Three dogs never experienced renal rejection before sequential islet transplantation (creatinine concentrations at islet transplantation 75, 77, 83 μmol litre^{-1}) yet their islet grafts functioned for only 7, 18 and 9 days respectively. All these dogs demonstrated mild renal impairment following sequential islet transplantation (*Table 3*). An example of the post-islet graft changes in plasma glucose, insulin and creatinine concentrations for one of these animals is illustrated in *Figure 1*. In this animal loss of glycaemic control was preceded by a fall in the plasma insulin concentration. The terminal rise in creatinine may have been due to either concomitant acute renal rejection or dehydration accompanying severe diabetes and glycosuria.

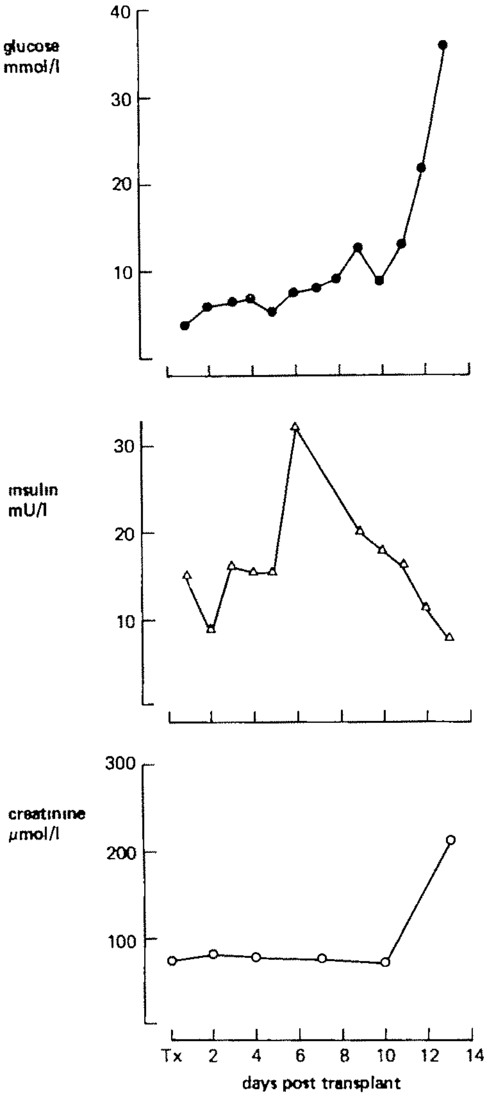

Figure 1 *Post-islet transplant changes in glucose (●), insulin (△), and creatinine (○) concentrations for one animal with no episodes of renal rejection before sequential islet transplantation*

Multiple previous episodes of reversible renal allograft rejection. Four dogs had experienced multiple episodes of renal rejection (median 3, range 2–4) including one within the 3 weeks preceding the islet graft (creatinine concentrations at islet transplantation 152, 157, 205, 311 μmol litre^{-1}). Their islet grafts functioned for 4, 14, 4 and 12 days respectively, with associated marked deterioration in renal function occurring in two animals (*Table 3*).

One episode of renal rejection. One dog had an episode of renal rejection 2 weeks after initial renal transplantation (creatinine rose from 72 μmol litre^{-1} to 199 μmol litre^{-1} in 2 days) The islet graft 10 weeks later maintained fasting normoglycaemia until the experiment was terminated because of severe weight loss and moderate renal impairment, 73 days after islet transplantation.

Deteriorating renal function occurred in most animals as a terminal event (*Figure 1*, *Table 3*). It was not possible to discern whether such deterioration in renal function was coincidental, occurred as a result of the islet transplant, or was a result of the diabetes which accompanied islet graft failure. In one animal renal rejection after sequential islet transplantation was reversed with a 3-day course of methylprednisolone, but islet graft failure followed. Steroid treatment was not given for presumed renal rejection following the islet graft in subsequent animals.

Effect of unilateral nephrectomy in donor animals

The plasma creatinine concentration rose significantly ($P < 0.001$) from 73·5 μmol litre^{-1} (range 57–101 μmol litre^{-1}) to 88 μmol litre^{-1} (range 76–104 μmol litre^{-1}) after unilateral nephrectomy.

Discussion

In this model of diabetes, prior donor specific renal transplantation has an adverse effect upon subsequent islet graft survival. The only significant difference between the two immunosuppressed groups at the time of islet transplantation was the presence of a prior renal allograft. The slightly higher creatinine level in group 3 at the time of islet transplantation, although not significantly different from group 2, was unavoidable; these animals were surviving on their transplanted kidney which, in many instances, had undergone episodes of rejection. It should be noted that in the animals acting as kidney donors unilateral nephrectomy resulted in a slight, but highly significant, rise in the plasma creatinine concentration Bolus steroid treatment reversed most episodes of acute renal rejection, but the plasma creatinine concentration rarely returned to its previous level. The diagnosis of rejection in these animals was based on clinical and biochemical findings only, supported by the response to steroids Other potential causes of a rapid deterioration in renal function, such as renal artery or vein thrombosis, would not have been amenable to treatment in these animal experiments Cyclosporin A nephrotoxicity has not been noted in dogs receiving considerably higher doses of cyclosporin A than were used in the present study[10,11]. Significant renal impairment would be more likely to have had an immunosuppressive effect than to have promoted islet graft rejection. Such impairment, as seen in this study, is unlikely to have influenced cyclosporin A pharmacokinetics. In dogs, as in man, urinary excretion is an unimportant route of cyclosporin A elimination[12].

The final eight dogs in group 3 were, to some extent, a selected group, being those which had survived for 3 months with renal allografts. The three animals which had never had episodes of renal rejection before sequential islet transplantation may have been particularly tolerant of their renal graft and rapid islet graft failure in these animals was unexpected. It was in these animals that prolonged islet graft function might have been anticipated. Sequential islet transplantation at a time of unstable renal function is clearly inappropriate, as shown by the outcome of those animals that had had multiple renal rejection episodes before islet transplantation. The mechanism of earlier islet graft failure following sequential islet transplantation remains unclear. In the cases of rapid islet graft rejection, recipient animals may have become sensitized to donor antigens with the second antigenic challenge (islets) resulting in islet, and in some cases renal, rejection.

Two areas require consideration before the results of these large-animal experiments are extrapolated to man.

The islet grafts prepared in the present experiments were relatively impure. Accurate assessments of islet graft purity were not performed, but we have previously reported a median graft insulin content of 26 per cent when using a similar method of graft preparation[13]. Quantification of islet yield by counting, with calculation of graft islet volume[14], is probably more accurate, but the limitations and difficulty of this technique with an impure islet graft are obvious. Gotoh *et al.*[15] reported unrefined rodent islet grafts to be rejected more quickly than pure preparations and suggested that contaminating tissues such as vascular or ductal fragments were a major stimulus to induction of acute rejection. It is conceivable, therefore, that a pure islet graft preparation might meet with a more favourable outcome after allotransplantation in both dog and man It has also been reported, however, that there is no difference between the rejection of pure and impure islet grafts in rodents[16].

The potential effects of islet cryopreservation, required in clinical practice, need to be considered. In the present experiments cryopreservation was not used, as the design of the study allowed islets to be maintained *in vivo* Techniques of canine islet graft cryopreservation do not yet allow reproducible and successful graft function following autotransplantation[5], and introduction of such a potential source of islet damage and variable function was not appropriate in these preliminary experiments. Cryopreservation is a potential method of islet immunoalteration and prolongation of rat to mouse islet xenograft survival by cryopreservation has recently been claimed[17]. Cryopreservation has not altered fresh or cultured human islet antigenic expression[18] and it is, therefore, unlikely that it would alter the outcome of human islet transplantation.

The marked disparity in the results of sequential renal and islet transplant experiments in rats[1,2] and these results for dogs are probably due to basic immunological differences between the two species. In the rat a short course of cyclosporin A treatment allows the establishment and long-term function of a renal transplant—a state of immune tolerance. In dogs a short course of cyclosporin A has allowed only slight prolongation of renal allograft survival and continued immunosuppressive treatment is required to allow long-term graft function[19]. Dogs are not tolerant of their renal allografts and sensitization to donor antigens may ensue, as suggested by the rapid failure of many of the sequential islet grafts in this study. Further work is required before attempting to adopt the single donor sequential renal and islet transplant scheme to clinical practice.

Attitudes of operating theatre staff to inoculation-risk cases

C. D. Johnson, R. Evans, D. C. Shanson and C. Wastell

Departments of Surgery and Medical Microbiology, St Stephen's Hospital, London SW10 9TH, UK

In a 12-month period, 177 patients at risk of infection with human immunodeficiency virus (HIV) or hepatitis B were operated on. Sixty-nine had HIV antibodies. The procedures used to identify these patients and minimize the risk of infection of hospital staff in the operating department are described. All staff working in the operating department were surveyed to determine their caseload, feelings of anxiety, and the incidence of high-risk exposure to infection. Anxiety was not related to workload, but was more common in those who had high-risk exposure. All members of staff who sustained a needlestick injury were tested for HIV antibodies at intervals after injury; 33 also volunteered to be tested in a screening session 3 months after the study period. None had HIV antibodies, suggesting that the risk of acquiring HIV infection in the operating department is low.

Keywords: Human immunodeficiency virus, hepatitis B, nosocomial infections, surgical technique

Surgeons, anaesthetists and theatre staff have faced the risk of inoculation with infective agents since surgery began. The present epidemic of human immunodeficiency virus (HIV) infections has increased awareness of this risk. Medical personnel exposed to blood, blood products and body fluids are also at risk of contracting hepatitis B, which is more readily transmissible than HIV infection[1] and is also found at increased incidence in the homosexual population.

Male patients with anorectal complaints constitute 10 per cent of new referrals to our general surgical out-patient clinic. In 1985, half of these were homosexual, of whom 38 per cent had evidence of one or other of these transmissible infections[2]. The catchment area of this hospital includes a large homosexual community. We see many patients who are potentially infected with hepatitis B, HIV and other sexually transmissible disorders

As a consequence of our catchment population, we operate on many patients who fall into an 'inoculation risk' group. Stringent precautions are taken to prevent infection of staff by inoculation with blood or other body fluids from these patients Our precautions are based on the Department of Health and Social Security (DHSS) guidelines for prevention of infection of hospital staff in general wards and in the operating theatre, for both hepatitis B[3] and HIV[4]. These guidelines should be adequate to protect operating theatre personnel if they are adhered to rigorously.

However, the implementation of the procedures may in itself increase the anxiety of the medical and nursing staff who are dealing with these patients. This paper examines our experience and its effects on the attitudes of operating department staff to their work with such patients.

Patients and methods

The following groups were deemed to be patients who posed an inoculation risk for HIV and hepatitis B homosexuals and bisexuals, all drug abusers, haemophiliacs, patients known to be HIV antibody or hepatitis B antigen positive, all cases of infective jaundice; patients from high-risk areas, such as central Africa, Haiti, certain parts of the USA, including visitors to those areas who have received blood transfusions there; any institutionalized person, and sexual partners and children of all these persons The number of such patients who were operated on in a 12-month period was recorded.

Patients at risk of these infections were offered hepatitis B and HIV antibody tests. Counselling was given and informed consent was obtained before testing for HIV antibodies All patients at risk were designated 'inoculation risk' with the exception of those whose risk factor was previous jaundice and who were known to be hepatitis B antigen negative. Inoculation risk cases were managed in the operating theatre in accordance with our hospital procedure, which is based on the DHSS guidelines[3,4] Copies of our detailed procedure are available from one of the authors (D.J.S.) At this hospital, we have designated a 'dirty' operating theatre. All inoculation risk cases and other infected cases are operated on in this theatre.

At the end of the study period, a survey was carried out of all personnel working in the operating theatres who might have been exposed to hepatitis B and HIV infections. These were the surgeons, anaesthetists, scrub nurses, anaesthetic nurses and operating department assistants. The survey questionnaire (*Table 1*) was designed by one of us (C.D.J.) to assess the degree of involvement of each member of staff in inoculation risk cases and to gauge their reaction to this workload The survey questionnaire was sent to each member of staff who was working in the operating theatre. Confidentiality was ensured by the following procedure. A numbered envelope was sent with each questionnaire, for its return The numbers were checked against a reference list, and reminders were sent as necessary When all questionnaires had been received, the reference list was destroyed, and the envelopes were opened No personal identification was possible from the completed questionnaires. The survey results were then presented at a meeting held in working hours in the operating department All members of staff present were invited to provide a blood sample to determine the prevalence of hepatitis B and HIV infections in the department Those who agreed had blood taken at once.

Results

In all, 5986 patients were operated on during the study period, of whom 177 were designated as 'inoculation risk'. Eight patients were hepatitis B risks only, and 169 were at risk for both hepatitis B and HIV, of whom 69 (41 per cent) had HIV antibodies. The remainder were equally divided between those with negative antibody tests, and those who refused testing. General surgeons treated 153 patients. The remainder were treated by various departments: gynaecology (three), orthopaedic surgery (two), dental surgery (thirteen), urology (five) and accident surgery (one).

Seventy-three questionnaires were sent to members of staff. Replies were received from 24 of 32 surgeons, 10 of 12 anaesthetists, 12 of 14 scrub nurses, and 12 of 15 anaesthetic nurses and operating department assistants (*Table 1*). Failure to reply after two requests was usually because the member of staff had left for other employment.

The relationships between exposure and anxiety were examined. There was no correlation between the self-reported caseload and anxiety, expressed as a reply of 'very anxious' or

Table 1 *Responses of operating department staff to the questionnaire*

1. How long have you worked at St Stephen's?

Surgeons ($n=24$)	15 months (2 months–15 years)
Anaesthetists ($n=10$)	8·5 years (2 months–22 years)
Scrub nurses ($n=12$)	11 months (2 months–4·5 years)
AN/ODA ($n=12$)	4 years (4 months–12 years)

(median and range values given)

2 How often do you personally deal with inoculation risk cases?

	≥3 per week	1 or 2 per week	1 or 2 per month	<1 per month
Surgeons	1	11	10	2
Anaesthetists	3	6		
Scrub nurses		10	1	1
AN/ODA	2	10		

3 Have you had a high-risk exposure* to hepatitis B or HIV infection at work?

Surgeons	9 (2 needlestick, 1 HIV, 2 hepatitis B)
Anaesthetists	5
Scrub nurses	0
AN/ODA	3 (2 needlestick, 1 HIV, 1 hepatitis B)

(*Needlestick injury, blood in eye, blood on skin)

4. How do you feel about dealing with inoculation risk cases?

	Very anxious	Uneasy	Not worried	Interested
Surgeons	2	15	5	3
Anaesthetists		10		1
Theatre nurses		8	4	
AN/ODA	4	4	3	4

(One surgeon and one anaesthetist felt both uneasy and interested One AN/ODA felt very anxious and interested; two AN/ODA were not anxious and interested)

5 Would you be happy to deal with: more cases, the same number or fewer cases?

	More cases	Same number	Fewer cases
Surgeons	4	8	12
Anaesthetists		1	9
Theatre nurses		2	9
AN/ODA		3	9

6. When looking for your next job, will the number of inoculation risk cases you would deal with be of no importance, of minor importance, affect your decision to take the job?

	No importance	Minor importance	Affect decision	No reply
Surgeons	6	11	2	5
Anaesthetists	3	4		3
Scrub nurses	1	7	4	
AN/ODA	3	3	6	

7. Does dealing with inoculation risk cases make you wish you worked somewhere else?

	Yes	No
Surgeons	7	15
Anaesthetists	3	7
Theatre nurses	3	9
AN/ODA	4	8

AN/ODA, recovery and anaesthetic nurses and operating department assistants

'uneasy' to question 4 Of 43 members of staff who dealt with one or more cases per week, 33 expressed anxiety, compared with nine of 13 who handled fewer than one case per week. In contrast, 32 of 43 members of staff with a reported caseload of one or more per week expressed a wish to do fewer cases, compared with five of 13 who dealt with fewer than one per week.

Anaesthetists uniformly expressed anxiety about handling inoculation risk cases, compared with 17 of 24 surgeons and 16 of 24 scrub nurses, anaesthetic nurses and operating department assistants. A history of high-risk exposure was associated with an increased expression of anxiety. Two surgeons who had sustained needlestick injuries were both uneasy, and two anaesthetic nurses or operating department assistants were both very anxious Of 17 staff who had had high-risk exposure (blood in the eye or on the skin, or a needlestick injury), 16 expressed anxiety, compared with 28 of 41 others Fourteen with high-risk exposure, compared with 25 of 41 without, expressed a wish to handle fewer cases. No member of staff who had a high-risk exposure has subsequently developed HIV antibodies.

Thirty-three members of staff (ten doctors and 23 nurses) provided a blood sample. All were tested for HIV antibodies and hepatitis B markers. All HIV tests were negative. Three nurses had hepatitis B core antibodies, indicating previous infection These individuals were all from the Indian subcontinent. No other member of staff showed evidence of hepatitis B infection.

Discussion

St. Stephen's Hospital serves a population with a large homosexual community. There is also a drug dependency unit in the hospital. In order to minimize the risk of nosocomial infection, the admitting doctor routinely asks a detailed sexual and drug history of all surgical patients. It is our experience that patients are usually willing to provide this information. Until one becomes used to it, such questions are frequently more embarrassing for the surgeon than for the patient. This policy identified 177 patients at risk of carrying hepatitis B or HIV in one calendar year. We feel that awareness of the possibility of HIV infection and specific enquiry to detect risk factors are major safeguards for the surgeon and the operating team.

We designated as inoculation risks all patients in groups at risk of HIV infection, irrespective of antibody tests. In contrast to those with hepatitis risk only, in whom a negative hepatitis B antigen test excludes infection, the absence of HIV antibodies cannot be taken as a guarantee of safety. In future, a reliable HIV antigen test that had been shown to correlate with HIV infection would enable us to exclude antigen-negative patients from the inoculation risk group.

The DHSS guidelines for handling inoculation risk patients in the operating department pose several constraints. For the operating team, the need to wear eye protection reduces visual fields. We find that transparent visors are more comfortable and less prone to condensation than goggles. We recommend that the surgeon wear two pairs of gloves while operating in the hope that this affords some protection against needlestick injuries. Most surgeons adapt quickly to wearing two pairs of gloves. For comfort, the second pair should be half a size larger. The recommendation to clean the theatre, and to allow it to stand empty for 1 h, effectively limits the number of inoculation risk cases to one per session. We have found it administratively easier to designate one theatre for all dirty and inoculation risk cases. No staff are allocated for this theatre: the surgical team transfers into the dirty theatre when necessary

It is for these reasons that we prefer to identify, by careful enquiry, patients at risk from HIV and hepatitis B infection and to take these extra precautions with those cases only. As others have pointed out[5], to apply these stringent additional precautions to every case would be inconvenient and expensive because of the increased use of disposable items, and it would greatly reduce surgical throughput. However, we have adopted the recent advice of the Royal College of Surgeons of England[6] to reduce the risk of needlestick injuries in all surgical procedures. Knives, needles and sharp instruments are not passed from hand to hand, but are laid in a dish and picked up by the recipient. Needles are held with instruments whenever possible.

It is arguable whether additional inoculation risk precautions should also be taken in all cases where a history is not available, for example when an emergency operation is done on an unconscious patient. We did not advise such a policy at the time of this study, but our previous experience of unwitting operations on hepatitis B carriers and the high prevalence of HIV in our catchment area have now led us to use full inoculation risk precautions in those circumstances.

The survey questionnaire was designed to determine how the staff perceived their inoculation risk workload, and its effect on them. This subjective assessment clearly has limitations. Workload was overestimated by the respondents, when compared with known numbers of cases and staffing levels. Subjective assessment of anxiety is probably only an approximation to the underlying level of anxiety, but is justified in this survey for three reasons: a simple questionnaire was used to encourage a high response rate; although self-reported feelings of anxiety were common they were likely to be an underestimate rather than an overestimate; and finally, we wished to establish people's perception of their situation, rather than some theoretically 'true' level of anxiety. The study showed no correlation between the self-reported rate of exposure, and feelings of unease or anxiety among department staff, although those with a high caseload were more likely to wish to perform fewer such cases. Therefore, the high incidence of reported anxiety in anaesthetists cannot be related only to their workload. Perhaps the nature of their work, with constant exposure to secretions, may contribute. Although a greater proportion of anaesthetists who replied were of consultant status than in other groups, the significance of this is doubtful because length of service in the hospital did not appear to have any relationship with expression of anxiety. Furthermore, all anaesthetists, junior and senior, were uneasy about inoculation risk cases.

The higher incidence of anxiety in those sustaining high-risk exposure to infection (needlestick injury, or blood spilt on the skin or in the eye) points to a need for counselling and education for these members of staff. If they can be reassured, then others may also worry less about potential risks.

It appears that HIV has a low infectivity in the hospital environment[1,7,8]. Nevertheless, it is worrying that we had so many high-risk exposures. Glove perforations and needlestick injuries are common[9,10], and their avoidance requires greater care in surgical technique and in the handling of used needles. Adequate protective clothing, including gloves for all personnel and surgical gowns with impervious sleeves, is essential. Our study confirms the low risk of these cases to theatre staff, despite the heavy workload. After 17 known high-risk exposures (with four needlestick injuries), there was no evidence of seroconversion from negative to positive antibody status for HIV, nor of infection with hepatitis B. The prevalence of HIV antibodies amongst medical and nursing staff who volunteered to be tested was zero, which also suggests that no member of staff was accidentally infected at work with this organism.

Although nine cases of occupational infection with HIV have been recorded in the literature, the risk is extremely low. In 1642 documented needlestick or blood splash exposures to HIV, there has been one seroconversion[8]. Three cases of seroconversion after surface exposure to blood all involved blood spilt on damaged skin or into the mouth, and two others were in women who provided long-term care at home for patients with AIDS[8]. Four nurses including one case mentioned above have undergone seroconversion after needlestick injuries[11–14]. All these occurred during the treatment of patients with AIDS or progressive generalized lymphadenopathy, all of whom were known to be HIV positive. These four cases all involved hollow needles, in some cases with syringe attached, and appear to have occurred during attempts to resheathe the needles. No instance of seroconversion after pricking with a surgical needle has been recorded, perhaps because a smaller volume of blood is introduced in such an injury.

We have no evidence that our attempts to reduce the risk of inoculation injury have prevented transmission of infection, but we feel it would be premature in our present state of knowledge to reduce these precautions in patients at risk of HIV or hepatitis B infection. The 29 per cent incidence of high-risk exposure to infection in our operating theatre staff would suggest, on the contrary, that we should make further efforts to reduce this exposure.

Post-splenectomy sequelae are now well recognized, and conservative splenic surgery is widely advocated. However, controversies exist regarding splenic surgical anatomy. We studied 127 human spleens using anatomical dissection and a sequential injection method involving both radiology and corrosion casting, with the primary aim of examining segmental splenic anatomy and blood supply. The existence of well-defined splenic segments was confirmed and these ranged in number from 3 to 7 with a mean of 4·3. Each segment had its own arterial supply and venous drainage. The segments were separated from each other by avascular planes. Subsegments with independent blood supply were also identified. The splenic artery was found to divide into two branches; in all cases these further divided into segmental arteries supplying the central segments of the spleen. The polar segments were supplied by segmental vessels of highly variable origin and size. This study aims to highlight the importance of identifying these segmental vessels at operation when splenic conservation is considered.

Keywords: Partial splenectomy, splenic blood supply, splenic segmentation

The phenomenon of post-splenectomy infection is now well recognized and many surgical techniques have been developed in an attempt to preserve splenic function. Recent studies suggest that partial splenectomy offers protection against pneumococcal sepsis[1–5]. While this is so, it remains a relatively rare operation, the main reason being that the spleen is a friable and highly vascular organ that can be difficult to mobilize, once haemorrhage has begun. Further advances in splenic conservation are dependent on better understanding of the vascular anatomy of the spleen.

The purpose of this study, therefore, was to identify accurately the segments of the spleen and their vascular supply.

Materials and methods

A total of 127 human spleens were studied, of which 50 were fresh post-mortem specimens; the remaining 77 were from dissection room cadavers. The spleens were isolated by division of the gastrosplenic and lienorenal ligaments and excision of the tail of the pancreas leaving splenic artery and splenic vein.

After removal, each spleen was studied using a number of techniques in a stepwise fashion. Firstly, macroscopic dissection was undertaken to identify the splenic vasculature and in particular the segmental vessels which were then cannulated to allow for the second and third stages of the procedure: radiological studies and corrosion casting. The following injections were performed (the number of investigations are given in parentheses): common splenic artery (8), common splenic vein (3), common splenic artery and vein (3), segmental arteries (26), segmental veins (3), segmental artery and vein simultaneously (10).

Radiological studies

Radiographs were taken with a mobile unit set at 3 kV for a 1·5 s exposure time at a distance of 0·914 m. The medium used was Conray Hypaque 420 (May and Baker Ltd., Dagenham, UK) which was injected into cannulae in a pattern as described above. Once the radiographs were completed, the cannulae were flushed with normal saline.

Corrosion casting

Using the same cannulae, injections were made using Batson's anatomical corrosion compound No. 17 (Polysciences Inc., Warrington, Pennsylvania, USA). Different colours were employed when individual segments were studied. Once injection was complete, the cannulae were clamped to prevent leaks and the spleens were submerged in water to allow the compound to take the natural form of the spleen. The cast material was then allowed to harden over 12–14 h. Each spleen was subsequently macerated in potassium hydroxide solution. The casts were then removed and any residual tissue washed away in warm water and detergent. Once the casts were dry they were photographed.

Results

Splenic vasculature

Common splenic artery: Figures 1 *and* 2. The splenic artery, henceforth referred to as the 'common splenic artery', arose as a single trunk from the coeliac axis in all but one case, where a second splenic artery was found arising directly from the aorta and supplying the upper pole. In the majority of specimens the artery was suprapancreatic, but in two cases it was retropancreatic and in one case it was intrapancreatic. The common splenic artery divided into a 'superior' and 'inferior' splenic artery in all cases.

Superior splenic artery: Figures 1 *and* 2, Table 1. The superior splenic artery was rarely a segmental artery and was usually

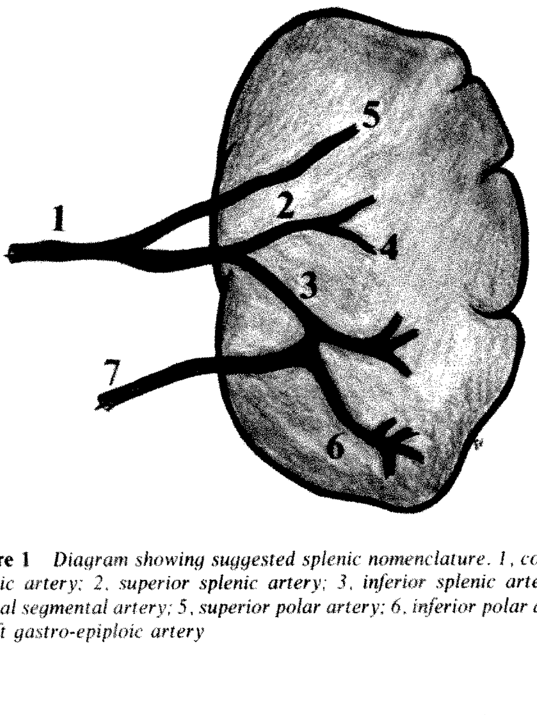

Figure 1 *Diagram showing suggested splenic nomenclature. 1, common splenic artery; 2, superior splenic artery; 3, inferior splenic artery; 4, central segmental artery; 5, superior polar artery; 6, inferior polar artery; 7, left gastro-epiploic artery*

divided into segmental branches which then supplied the superior central segments of the spleen. In 60 per cent of specimens it gave off a branch to the superior pole of the spleen, which we termed the superior polar artery. It also gave off fundic branches to the stomach and, in one specimen, the left gastro-epiploic artery.

Inferior splenic artery: Figures 1 *and* 2, Table 1. The inferior splenic artery was smaller than the superior splenic artery. In the majority of specimens it divided into two segmental arteries supplying the inferior central segments. It gave origin to the inferior polar artery and the left gastro-epiploic artery in 28 and 3[illegible] per cent, respectively, of specimens studied.

Segmental arteries: Figure 1. Early studies showed the existence of well-defined segments within the spleen. The segmental vessels were either central or polar depending on the area of spleen they supplied.

1. *Central segmental arteries.* These vessels, like the polar arteries, took origin from the superior and inferior splenic arteries. Those arising from the former supplied the superior central segments, and those from the latter, the inferior central segments.
2. *Polar segmental arteries.* These vessels had a highly variable origin supplying the superior and inferior polar segments of the spleen.

Superior polar artery: Figure 2, Table 1. The superior polar artery supplied the superior polar segment. It was the more tortuous of the two polar vessels. Those having a proximal origin (36 per cent) arose from the superior splenic artery in 60 per cent of cases, the common splenic artery in 40 per cent of cases and in one instance from the aorta directly. Those originating distally (64 per cent) always arose from the adjacent superior central segmental artery, and were much smaller vessels than those arising proximally.

Inferior polar artery: Figure 3, Table 1. The inferior polar artery is always a segmental artery, having either a distal or a proximal origin. Those having a proximal origin (75 per cent) arose from either the common splenic artery (14·5 per cent), the inferior splenic artery (28 per cent) or the left gastro-epiploic artery (57·5 per cent). Those arising distally (25 per cent) always arose from the adjacent inferior central segmental artery.

Subsegmental vessels: Figure 1. Segmental arteries were found to divide into subsegmental vessels usually within the splenic capsule, but occasionally outside the splenic hilum, a pattern more common among the polar arteries and in those spleens containing many notches.

Patterns of splenic blood supply

There were three main patterns of blood supply. Firstly, and most commonly, the segmental arteries entered the hilum to supply their corresponding segments. In the remaining specimens the segmental vessels divided into subsegmental branches before entrance, or the superior and inferior splenic vessels entered the hilum directly before dividing into segmental vessels.

Common splenic vein. The pattern of vasculature for the splenic vein showed remarkable similarity to the artery. The veins ran a course identical to that of the segmental arteries, uniting to form the splenic vein which was retropancreatic.

Splenic segmentation: Figures 4–7. The existence of well-defined vascular segments in the spleen was suggested by radiological studies, further supported by corrosion casting and confirmed by microscopic examination of the intersegmental boundaries of the casts. These segments were defined as

anatomically distinct areas of splenic tissue running from the anterior to the posterior border, perpendicular to the long axis of the spleen. They ranged in number from three to seven (mean 4·3). There were two morphological types of segment—central and polar. The central segments were wedge-shaped in outline and larger than the polar segments. The number of these segments found in each spleen was variable (from one to five). Polar segments were pyramidal, located at the superior and inferior poles of the spleen, and were a constant finding.

On further study it was noted that each segment consisted of a number of 'subsegments'. There were three such units in polar segments and four in the central segments (*Figure 4*).

Spleniculi. When identified, spleniculi were also studied. They were present in 4 per cent of specimens and most commonly located in the gastrosplenic and lienorenal ligaments. Radiological and corrosion cast studies of these mesenchymal aggregates revealed them to have a striking similarity to subsegmental units in the spleen, both in blood supply and size.

Notches. Notches were found on the anterior and posterior borders, being more common along the former (range 1–7). The posterior border contained a maximum of two notches and frequently had none. Although the notches on the anterior border correlated well with segmental boundaries, this relationship was inconsistent.

Discussion

This study confirms the segmental nature of splenic anatomy, each segment being clearly separated from those adjoining it and having an independent arterial supply and venous drainage. It further demonstrates that these segments are composed of 'subsegmental units', each with an isolated blood supply.

The notched appearance of the spleen, not surprisingly, suggested splenic segmentation and this concept was evaluated as early as 1870 by Kyber[6] who described the spleen in man, cat, dog, horse and rabbit as being divided into several segments by 'fibrous septa'. Tait and Cashin[7] confirmed this in the dog and cat and in 1952 Dreyer and Budtz-Olsen[8] carried the concept a step further when they discovered separate venous segments while carrying out portal venography. Braithwaite and Adams[9], using radio-opaque dye injection, were the first to note that each splenic segment had its own arterial supply and venous drainage.

Recently, corrosion casting techniques have formed the basis for more detailed splenic segmental studies. While such studies confirm the existence of splenic segments they differ in their observations. Clausen[10], Gutierrez-Cubillos[11] and Gupta *et al.*[12] reported the existence of from two to four segments. Studies by Mikhail *et al.*[13] revealed up to five splenic 'lobes' while Voboril[14] found as many as ten splenic segments with a mean of six. Although splenic segmentation is now undisputed,

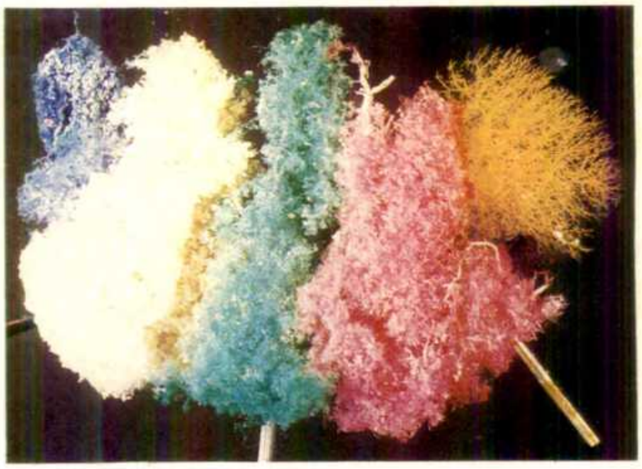

Figure 6 *Cast of a spleen containing five segments. Blue and yellow, polar; white, green and red, central. Note the avascular planes between segments*

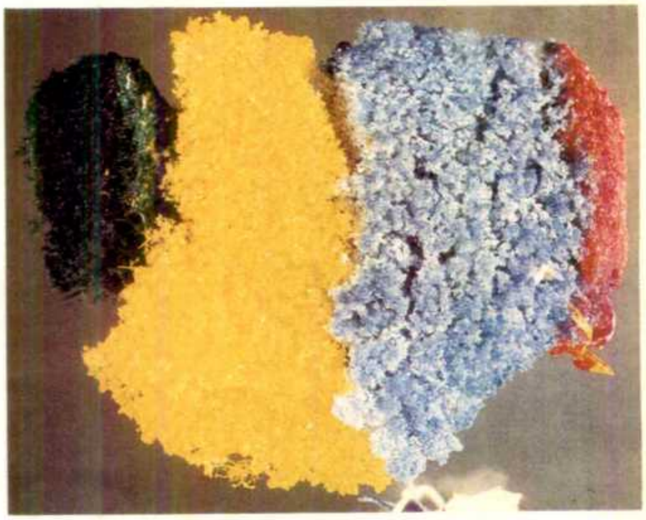

Figure 7 *Cast of a spleen containing four segments. Green and red, polar; yellow and blue, central*

there remains a lack of consistency in the literature regarding the exact morphology of these segments, their number and blood supply. We believe that lack of agreement on splenic segmental anatomy, as demonstrated above, is because of incomplete methodology and suggest that the segmental anatomy of the spleen can only be properly evaluated using a combination of techniques, as individual techniques have significant shortcomings.

With these points in mind, we studied the segmental anatomy of the spleen with the aid of macroscopic dissection, radiological studies and corrosion cast studies, using these techniques in a segmental stepwise fashion. As a result this study clearly identifies the existence of splenic segments; it defines them and classifies each one as either wedge-shaped (central) or pyramidal (polar). Synchronous injection studies of the segmental arteries and veins have further demonstrated the arterial and venous territories to have identical boundaries.

These further refinements of examination have led to the identification of 'subsegments', i.e. segments within segments with independent blood supply and venous drainage. The existence of these subsegments may have embryological relevance. When casts of subsegments were compared with those of accessory spleens or spleniculi, they were found to be similar both in appearance and in blood supply. This may imply that the embryological development of the spleen involves the amalgamation of these small units of splenic tissue (subsegments = spleniculi) to form segments and ultimately the entire organ. Any such units remaining, not incorporated into the organ, are isolated as accessory spleens or spleniculi.

Discrepancies also exist between previous studies regarding splenic blood supply[12,13]. The findings of this study indicate that the blood supply of the spleen has a predictable distribution depending on the number of segments present. This allows for clearer definition of splenic vascular anatomy than has hitherto been available. We suggest that the introduction of specific nomenclature as follows would facilitate the identification of splenic vasculature.

The 'common splenic artery' arises almost invariably from the coeliac axis in a common stem with the hepatic artery. It has two constant branches, the superior and inferior splenic, which subsequently divide into segmental arteries. Whereas central segmental blood supply is constant in origin, polar segmental supply is more variable, both in origin and vessel calibre. The other variable in splenic blood supply is the degree of incorporation of the division of the subsegmental and, to a lesser extent, the segmental vessels inside the hilum of the organ. This is responsible for the numerous patterns of vessel division found outside the splenic hilum, as referred to above.

We believe that the differences in opinion in the literature are a result of the misinterpretation of these very definite patterns of blood supply, coupled with the over-emphasis placed on recognition of segments from whole arterial or venous casts. This study demonstrates clearly the existence of definite patterns of splenic blood supply and offers a nomenclature in an attempt to clarify these. Finally, it implicates the segmental vessels as those with the greatest surgical importance and stresses that their early identification at operation for trauma should lead to increased splenic conservation.

A retrospective analysis of 23 cases of amoebic liver abscess with intraperitoneal rupture is presented. Group I consisted of 16 patients with clinical features of generalized peritonitis. Eight of these patients were treated surgically, and four died. Group II consisted of seven patients with features of localized peritonitis and all were treated conservatively. In all cases the diagnosis of liver abscess was established by liver scan or ultrasound examination; peritonitis was established either at operation or, in the conservatively managed group, by aspiration of pus from the peritoneal cavity. Amoebiasis was diagnosed by serology. Eight group I and all group II patients were managed conservatively by aspiration of the liver abscess, antibiotics and amoebicides. There were no deaths in this group. It is suggested that, if the diagnosis can be made early, conservative treatment offers the best chance of cure for patients of amoebic liver abscess with intraperitoneal rupture.

Keywords: Liver abscess, amoebiasis, rupture, intraperitoneal

Liver abscess is the commonest extraintestinal manifestation of amoebiasis, a disease prevalent throughout tropical and subtropical countries. Peritonitis secondary to rupture constitutes the second most common complication of amoebic liver abscess after pleuropulmonary amoebiasis. Spontaneous rupture of amoebic liver abscess into the peritoneal cavity is reported in 2·5–17 per cent of patients[1], and the condition is frequently fatal with an associated mortality rate of up to 75 per cent[2]. Management of this complication of amoebic liver abscess has remained controversial. We present our experience with 23 cases of spontaneous rupture of amoebic liver abscess into the peritoneal cavity.

Patients and methods

Between 1981 and 1986, 240 cases of amoebic liver abscess were diagnosed and treated at our hospital. A retrospective analysis revealed that 23 of these cases had a spontaneous rupture of the abscess into the peritoneal cavity. The age and duration of symptoms at presentation, prodromal symptoms of fever and ill health with or without diarrhoea, and pain in the right upper abdomen were recorded. On the basis of signs at presentation the patients were divided into two groups: group I consisted of 16 patients with features of generalized peritonitis; group II consisted of seven patients with features of localized peritonitis.

Laboratory investigations included haemogram, liver function tests, stool examination and amoebic serology (haemagglutination test). The diagnosis of liver abscess was confirmed by Rose Bengal or technetium-99 hepatic scan. Diagnosis of peritonitis was based on the aspiration of pus from the peritoneal cavity in all cases. Since 1983 ultrasound examination has been used.

The indications for surgery included: (1) peritonitis when a liver abscess was not suspected; (2) failure to respond to conservative management; and (3) secondary infection. The surgical procedure consisted of drainage of pus from the peritoneal cavity and the liver abscess, a thorough peritoneal toilet with normal saline, and insertion of drains before closure of the abdomen. Other measures included administration of metronidazole and broad-spectrum antibiotics, followed by 21 days of chloroquine therapy. The remaining patients were managed conservatively with intravenous or oral metronidazole, antibiotics and needle aspiration of the liver abscess, with a follow-up treatment with chloroquine. All patients were followed up with hepatic scans and/or ultrasound examination to assess the response to treatment.

Results

The age of the patients ranged from 12 to 59 years; males were predominantly affected (male:female ratio, 19:4). The duration of symptoms at presentation ranged from 8 to 26 days. A history of ill health and fever (18 patients), diarrhoea (13 patients) and pain in the right lower chest and right upper abdomen (16 patients) were the most frequent symptoms. Amongst group I patients, five cases presented to the hospital with features of generalized peritonitis and two patients were referred from other centres in a moribund condition after failing to respond to conservative treatment; in one patient there was evidence of secondary infection in the aspirated pus. These eight patients underwent operation. In four of the remaining eight cases in the group, the diagnosis of a ruptured amoebic liver abscess was suspected because of tender hepatomegaly and ultrasound demonstration of a liver abscess. The other four patients developed features of peritonitis during the course of inpatient treatment of liver abscess. These eight cases were treated conservatively. The seven patients in group II were being treated at the hospital with a diagnosis of amoebic liver abscess and developed features of localized peritonitis confirmed by aspiration of pus from the peritoneum; these patients were also managed conservatively.

Laboratory investigations revealed leucocytosis ranging from 9500 to $26\,000/\text{mm}^3$ (mean $16\,000/\text{mm}^3$). The serum bilirubin was normal in 19 patients; in the remaining four cases serum bilirubin levels ranged from 3·2 to 5·6 mg/dl. The serum alkaline phosphatase (normal 3–13 KAU) was elevated in ten patients (range 17–347 KAU; mean 57 KAU) while the serum glutamic oxaloacetic transaminase/serum glutamic pyruvic transaminase was normal (40/40 units) in 17 cases and only minimally raised (maximum 90/95 units) in six cases. The serum albumin levels were below normal in 12 patients with a mean of 2·9 g/dl. The amoebic haemagglutination titre was determined in 22 patients and ranged from 1:1680 to 1:116 000 (considered positive if more than 1:512).

Hepatic scan (21 cases), ultrasound examination (11 cases) and computed tomography scan (one case) revealed that all patients harboured the abscess in the right lobe. In 21 cases the abscess was solitary while in two cases two abscesses were present. In all cases the abscess cavities occupied the superior portion of the right lobe.

All patients treated conservatively improved and follow-up hepatic scans revealed resolution of the abscess cavities within 3 months of discharge from the hospital. There was a high mortality rate in the surgically treated group with four patients succumbing to the disease. These included one patient with secondary infection who died from septicaemia, two patients who had failed to respond to conservative treatment and who died from their poor general condition, and another patient who developed multisystem organ failure with severe bleeding ten-

0007-1323/89/020202-02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

dency postoperatively. The overall mortality rate from amoebic peritonitis was 17 per cent while it was 25 per cent in patients with generalized peritonitis. The duration of hospital stay was 11 ± 2 days for the surgically treated patients and 16 ± 3 days for those managed conservatively.

Discussion

Amoebic peritonitis following intraperitoneal rupture of a liver abscess is a serious complication. The reported incidence of this complication varies from 2·4 to 17 per cent[1,3–6]. In this series it was 9·6 per cent. This dreaded complication of amoebic liver abscess has been associated with a high mortality rate in the past, approaching 75 per cent[2,4,6]. The factors attributed to the high mortality are delayed or inadequate treatment[6,7], poor nutrition or diminished host resistance prevalent in most tropical countries associated with other diseases[6], and secondary infection with septicaemia[8]. The other poor prognostic signs are generalized peritonitis, jaundice, and the presence of multiple abscesses[4,9–11]. The causes of a 17 per cent mortality rate in the present series were delayed diagnosis, poor host resistance and septicaemia.

The diagnosis of the disorder may be difficult; in the present series the diagnosis was missed in 31 per cent of the patients presenting with generalized peritonitis. A high index of suspicion should always be maintained, especially in tropical countries. A useful pointer is the occurrence of the disorder almost exclusively in male patients[4] (83 per cent in the present series). A tender hepatomegaly, preceding history of diarrhoea, and a raised right dome of diaphragm may suggest an amoebic aetiology for the peritonitis[1] as was the case in the patients under review. A syndrome of abdominal pain of 'prerupture' has been described which may precede the development of peritonitis[12] although others point out that acute symptoms may be present without actual rupture[13]. Thus a correct diagnosis is often missed[1,11,12,14]. The pitfalls in the correct preoperative diagnosis as reported in literature have been analysed by Archampong[6] who observed that a preceding history of dysentery and of prolonged ill health may be absent whilst in endemic areas the common association of intercurrent disease may blur the picture, and that abdominal pain may not be confined to the right hypochrondrium before rupture.

Although the superior surface of the right lobe of the liver is the commonest site of involvement, abscesses that rupture into the peritoneal cavity usually involve the inferior surface of the liver[4]. Rupture is seen in a higher percentage of abscesses occurring in the left lobe of the liver[6,12,15–17]. The reasons cited are the smaller bulk of the left lobe which is unable to contain the rapidly expanding abscess, the complete peritoneal coverage of the left lobe and its anatomical relations which prevent the formation of firm adhesions, and a delay in the diagnosis of abscess located in this situation. However, in the present series all abscesses which ruptured were situated in the superior surface of the right lobe. Sudden rupture leads to generalized peritonitis while a slow leak allows formation of adhesions leading to localized peritonitis.

Conflicting opinions have been expressed concerning the treatment of amoebic liver abscesses which rupture into the peritoneal cavity. The indications for surgical intervention for amoebic liver abscess are, indisputably, left lobe abscesses and abscesses that are secondarily infected. However, there is no clear consensus regarding treatment of intraperitoneal rupture of amoebic liver abscesses. Since 1892, when Hulke first described successful operative treatment of such a case[14], many reports have appeared of surgical treatment of the disorder with good results[1,6,18–21]. However, since DeBakey and Ochsner's reports of 100 per cent mortality rate in patients treated surgically[4] many authors have stressed conservative measures[6]. The effectiveness of conservative treatment has been enhanced by the routine use of metronidazole which has been associated with the disappearance of the abscess cavity even without drainage, as demonstrated by repeated hepatic scans[22]. The present data would support these observations in that the mortality rate in surgically treated patients with generalized peritonitis was 50 per cent compared with a mortality rate of zero in patients managed conservatively. However, it is pertinent to emphasize that all the deaths occurred in patients in whom diagnosis was delayed and whose general condition was moribund. Thus, even though operative mortality has been reduced from 75–100 to 40–50 per cent[1] because of improved anaesthesia, resuscitative measures, antibiotics and antiamoebic drugs, data suggest that timely institution of conservative measures, particularly the use of metronidazole[2,6], offers the best chance of cure to patients with intraperitoneal rupture of amoebic liver abscesses, as was the case in the present series.

That amoebic liver abscess rupturing into the peritoneal cavity can kill is established, and this is corroborated by the death of 17 per cent of the patients under review. However, if a diagnosis is made early and antiamoebic treatment started, non-operative management can produce effective and gratifying results.

The need for dressings on clean and clean contaminated surgical wounds was investigated. A total of 1202 patients with 1202 clean or clean contaminated surgical wounds were randomized into two groups: 633 wounds were covered by dressings up until the time of suture removal, and 569 wounds were treated without dressings after the first postoperative day. In the group characterized by long dressing time, the rate of postoperative wound infections was 4·9 per cent. The rate was 4·7 per cent in the group represented by short dressing time. Using short dressing time not only reduces the number of nursing hours but also limits the need for costly dressing material. In addition, both wound observation and patients' personal hygiene are made easier.

Keywords: Postoperative care, surgical equipment, wound healing, wound infection, surgical nursing

The covering of the primarily sutured surgical wound with a sterile dressing is ordinarily considered to be a routine conclusion to an aseptic operation. Most often, the wound is left dressed until the sutures are removed.

Purposes for wound dressings are: (a) absorption of wound secretions; (b) protection of the wound from injury; and (c) protection of the wound against bacterial contamination.

Experimental studies[1,2] have shown that the carefully sutured incision with haemostasis is sealed by fibrin within 6–24 h and that the wound hereafter becomes effectively protected against outside moisture and bacterial contamination.

It has not been proved that conventional dressings are capable of preventing the access of bacteria to the wound, nor that carefully sutured surgical wounds with haemostasis need this protection after 24 postoperative hours.

Previous clinical investigations have dealt with this issue partly by retrospective accounts of surgical wounds treated without dressings[3–5] and partly from comparative testings based on limited material[6–8]. Experimental tests have demonstrated a uniform healing between dressed and undressed surgical wounds[2].

At the present time, however, there are no published results of clinical investigations based on statistically sufficient material.

Patients and methods

The investigation was prospective and randomized. It was carried out on the surgical wards of Kalundborg General Hospital and Saeby General Hospital in the period from 1 November 1984 to 31 December 1987.

Before surgery, all patients were informed both verbally and in writing. Only those who gave their consent were entered. Patients under 3 years of age were exempt as were those with casts or any other type of immobilizing bandage.

The surgeon classified the wounds postoperatively as clean, clean contaminated, contaminated, or dirty, as indicated by Cruse[9]. Patients with clean or clean contaminated wounds were then randomly divided into two groups, according to their dates of birth: (a) even birth-date numbers: sterile dressings were applied to the wound from the end of the operation until the sutures were removed; (b) uneven birth-date numbers: sterile dressings were applied to the wound during the first 24 h, therafter being removed and the area left uncovered.

Drain sites were covered with sterile gauze until the drains were removed.

Patients' sex, age, height and weight were recorded. A patient was classified as being overweight if his weight in kilograms was greater than or equal to his height in centimetres minus 82. Height and weight were recorded in 1159 patients of whom 89 were overweight.

All patients were permitted to shower from the first postoperative day. Patients with dressings had them protected with a covering of plastic.

On suture removal, all cicatrices were examined for any signs of infection. A wound was defined as being infected by secretion of pus from the cicatrix, suture canals, or subcutaneous abscess.

Results

In all, 1325 patients were randomized. In 91, there was insufficient information at the time of removal of the sutures: 21 patients were incorrectly randomized; eight patients were withdrawn due to allergic reactions to the dressing material, and three patients died during the observation period. Thus 1202 patients remained for the final analysis.

Tables 1 and *2* show the distribution of patient characteristics, the total incidence of wound infections, and the operations performed. Overweight patients had a significantly increased infection rate, with nine of 89 obese patients developing wound infections (χ^2 test, $P=0{\cdot}021$). Sex, age or the degree of contamination had no significant influence on the infection rate.

Table 3 shows the incidence of wound infection in patients with long and short dressing times. There is no significant difference between the infection rate in the two groups. In 1·8 per cent of the wounds there was an accumulation of pus that required surgical drainage. In the remainder of the infected wounds the infection did not influence treatment.

Table 4 shows the number of patients in the two treatment groups who received a dressing change on the ward, together with the reasons for that dressing change; 108 patients performed their own dressing change after discharge from hospital.

No patient without a dressing needed to have one applied as a result of secretion from the wound or injury to it.

Table 1 *Distribution of patients in the randomized groups*

	Total	Wound dressed	Wound exposed	Infected wounds
No. of patients	1202	633 (52·7)	569 (47·3)	58 (4·8)
Clean wounds	876	465 (53·1)	411 (46·9)	42 (4·8)
Clean contaminated wounds	326	168 (51·5)	158 (48·5)	16 (4·9)
Women	629	331 (52·6)	298 (47·4)	26 (4·1)
Men	573	302 (52·7)	271 (47·3)	32 (5·6)
Age <50 years	721	360 (49·9)	361 (50·1)	31 (4·3)
Age ⩾50 years	481	273 (56·8)	208 (43·2)	27 (5·6)
Not overweight	1070	556 (52·0)	514 (48·0)	49 (4·6)
Overweight	89	54 (61)	35 (39)	9 (10)

Others	14 (2·2)	— —
Total	206 (32·5)	16 (2·8)

Figures in parentheses are percentages. * Dressing during the first 24 postoperative hours

Discussion

The results of this investigation show that clean and clean contaminated primarily sutured wounds treated by the application of a dressing during the first 24 h after operation and thereafter left undressed do not have an increased incidence of wound infection in relation to the same type of wounds which are dressed until suture removal. Previous studies have shown the same result, but either the investigations have not been controlled[3–5] or the material has been too limited and the patients not randomized[6–8].

Some authors stress the risk of cross-infection on the ward[10–13]. If a conventional wound dressing protects sutured surgical wounds against this risk after 24 postoperative hours then the infection rate would have been higher in those patients who were treated without dressing. We can therefore conclude that either the dressing adds no protection against cross-infection, or the risk of cross-infection is low and non-existent during the investigation period.

Routine treatment of sutured surgical wounds with dressings is based on tradition and is not scientifically supported. The advantages of omitting a dressing after the first 24 postoperative hours are: (a) the wounds can be easily examined with no unnecessary inconvenience to the patient, and the earliest signs of wound complications can be noted; (b) the method not only reduces the number of nursing hours used to change dressings but also limits the need for dressing material; and (c) patients without dressings are more easily able to carry out their personal hygiene. The presence of a 24-h-old sutured wound is not a contraindication to washing or showering[3,8,14].

Enterostomy as an adjunct to treatment of intra-abdominal sepsis

Sir

We were interested to read the paper by Hesp *et al.* (*Br J Surg* 1988; **75**: 693–6). However, we were surprised to read that no data concerning the results of this technique were available in the literature.

In the Surgical Digestive Intensive Care Unit of the Hôpital Saint-Antoine, Paris, France, temporary enterostomies have been used since 1969 for this indication[1]. Many papers describing the results of this approach, together with the technique of chyme reinfusion, have been published in both French and English literature[2,3]. It is disappointing to see that the information on this subject does not appear to have been exhaustively researched before publication.

Anatomical nit-picking?

Sir

In a survey of 30 anatomical or surgical textbooks regarding the surface anatomical marking of the deep inguinal ring, 14 stated that it was at the mid-inguinal point and nine that it was at the mid-point of the inguinal ligament. Six books gave no surface marking for the deep ring and one modestly or perhaps correctly stated that it was difficult to be sure.

The other structure positioned at either of those two landmarks is the femoral artery and, again, with this the picture is almost as confused, with 18 putting it at the mid-inguinal point and only five at the mid-point of the inguinal ligament.

The difference between the mid-inguinal point and the mid-point of the inguinal ligament is often practically non-existent (even a modest covering of adipose tissue can make the bony points difficult to locate without causing undue discomfort to the patient) and, therefore, it seems a rather archaic and even futile exercise to retain the two as separate entities. To be pedantic, the mid-inguinal point should actually be just above the inguinal ligament and thus pulsation felt at that point would be that of the external iliac artery and not the femoral artery.

Surely it would be sensible to favour a more pragmatic approach, and teach students that when feeling for femoral artery pulsation and when attempting to occlude the deep ring in examination of hernias, they should use two fingers and therefore actually cover both anatomical points?

Growth rates in hepatic metastases

Sir

We would like to make some comments on the paper by Finlay *et al.* (*Br J Surg* 1988; **75**: 641–4) on growth rates in hepatic metastases.

First, the formula for volume appears to be incorrect. There should be three length dimensions in any volume formula; for example, a spherical metastasis with diameter a would have volume $V=\frac{\pi}{6}a^3$, an oblate or prolate ellipsoid with diameters a and b would have volume $V=\frac{\pi}{6}ab^2$ and a triaxial ellipsoid with diameters a, b and c would have volume $V=\frac{\pi}{6}abc$. Should the formula given be volume $V=\frac{\pi}{6}ab((a+b)/2)$?

Second, although it is stated that at least three serial volume measurements were made for each patient and metastasis, only two points are shown for most of the growth curves in *Figures 1* and *2* and *Tables 1* and *2*. The instantaneous doubling time calculated depends on whether the exponential parameter was estimated from all serial data points or from just two, in which case, which two? The way dt differs from the first two data points to the last two may give some support to using the Gompertz equation as it would imply that dt is changing with volume.

Third, there are some important discrepancies between the data given and the statistical conclusions. Correlation coefficients are normally expressed in a range from -1 to $+1$ so it is not clear what a value of 90·54 means: is it a percentage? Indeed, were it not for a missing extreme value on the scatter plot (*Figure 3*), the correlation would not be significant, as is the case for overt and occult taken separately. While the overall values for growth rates seem plausible, the distinction between overt and occult seems entirely artificial and the difference in Dt between them is not significant ($P<0{\cdot}07$ Mann–Whitney U test).

Finally, as stated, back extrapolation is such a precarious exercise that one wonders about the usefulness of the information which is gained in this way.

Surgical glove perforation

Sir

I read with interest the paper by R. D. A. Dodds *et al.* concerning surgical glove perforation (*Br J Surg* 1988; **75**: 966–8). It is disturbing that in 50 per cent of cases they found that the surgeon was unaware that a perforation had occurred. This figure is comparable with the experience of other authors[1,2]. Gloves may even be perforated before being donned.

In the light of the ever increasing number of HIV- and hepatitis B-positive patients, it would be most desirable to be made aware of a glove puncture as soon as it occurred so that gloves could be changed immediately, thus preventing prolonged contact of the patient's body fluid with the surgeon's skin. Likewise, cotton gowns and drapes are not impervious to organisms, particularly when they are wet[3].

An electronic device intended to detect direct contact of the patient's body fluids with the surgeon's skin has been described, where a breakdown in the normal very considerable electrical resistance between surgeon and patient, as a result of direct fluid contact between the two, causes an audible alarm to sound[4]. I am able to report preliminary experience of its use in 51 cases.

The alarm sounded 41 times in 17 cases, the maximum number per case being five. Glove punctures (determined by inflation under water) were responsible on 11 occasions (five when double-gloved, i.e. punctures through both pairs), and damp gown sleeves touching the wound caused 29 alarms. The device sounded only once without explanation.

The device, which is simple to use, could have application when operating on 'high-risk' patients, as well as in prosthetic surgery where small inoculi of normal commensal organisms may cause serious postoperative sepsis.

It has been suggested that the wearing of double gloves confers additional protection to the surgeon against contact with the patient's body fluids[5]. Double gloving is not, however, universally acceptable, with possible discomfort and reduced sensitivity and dexterity leading to the surgeon removing his gloves in 26 per cent of cases[5].

The use of this device would allow the surgeon to wear a single pair of gloves if he so desired, being warned as soon as a perforation came into contact with the patient's body fluid, even if he did not feel anything when the puncture occurred. The device has also been shown to be capable of detecting punctures through two pairs of gloves, and in addition warns of wet gown sleeves touching the wound, of which the surgeon may be unaware. The latter was detected on almost three times as many occasions as gloves puncturing. Fluid leakage through gowns has largely been ignored in recent publications concerning surgeons' safety[5,6].

Branchial cysts in the parotid gland

Sir

We enjoyed the paper by Wyman and his colleagues (*Br J Surg* 1988; **75**: 818–19) which draws attention to branchial cysts within the parotid gland. It is a pity that they give no indication of the incidence of the condition as we believe it to be rather higher than previously reported. We found five cases out of 133 consecutive parotidectomies, an incidence of 3·8 per cent[1]. It is implied that preoperative diagnosis cannot easily be made but, with clinical awareness of the condition supported by ultrasound scanning and needle cytology, the condition can be diagnosed before surgery.

We agree that the lymph node or inclusion hypothesis is the most likely explanation for branchial cysts within the parotid. While of interest, this has little influence on diagnosis or treatment. Most of these cysts will probably continue to be found by chance in superficial parotidectomy specimens, but awareness of their existence may allow more to be treated by simple cystectomy alone.

Since our report we have detected another case preoperatively.

Graft–enteric fistula

Sir

We read with great interest the paper by Tilanus *et al.* on the diagnosis and management of graft–enteric fistula (*Br J Surg* 1988; **75**: 915–6). The authors confirmed the appalling mortality from this condition and report one survivor of ten patients who underwent graft excision and subsequent extra-anatomic bypass for graft–enteric fistula of the proximal anastomotic line. Greater success was reported with local treatment for the distal anastomotic line (five out of six survivors).

We agree that every patient who presents with blood loss in the gastrointestinal tract after vascular prosthetic implantation needs a thorough work-up and laparotomy to exclude the diagnosis of graft–enteric fistula. We support the authors' view that gastroduodenoscopy is the most important preoperative diagnostic test which may not only exclude other more common causes of gastrointestinal haemorrhage, but may also actually visualize the graft in the fourth part of the duodenum. Arteriography is rarely helpful in the diagnosis of this condition when the patient is stable. We have found that CT scanning is of considerable help and in our experience the fistula may be imaged by this technique.

Surgical intervention for aortoenteric fistula is mandatory since eventual exsanguination is inevitable. Most series suggest that there is usually a significant time period between diagnosis and operation when the patient is stable. This gives the surgeon an opportunity to plan the best management of such cases. The removal of all prosthetic material combined with adequate postoperative drainage remains the procedure of choice. Protection of the distal circulation by extra-anatomic bypass (usually axillobifemoral bypass) is recommended. In contrast to Tilanus *et al.* we believe that extra-anatomic bypass should be inserted under aseptic conditions before exploratory laparotomy and graft excision. By this method the mortality rate may be reduced to around 17 per cent[1]. Two such cases have recently been managed by this method with success.

To prevent aortic stump blow-out we meticulously oversew the aortic stump with interrupted monofilament sutures followed by a continuous layer and finally a seromuscular patch using the anterior longitudinal spinal ligament. Adequate postoperative drainage and suitable antibiotic cover are mandatory.

Prevention of this aortoenteric fistula remains the primary goal. In particular it is vital to protect the suture line either by wrapping the aneurysmal sac around the prosthesis, or by interposing omentum between the bowel and graft. Strict asepsis during aortic procedures is mandatory and if the bowel is transgressed for any reason then the operation is best abandoned. Once the diagnosis of aortoenteric fistula is diagnosed or suspected, early aggressive surgery remains the only hope for decreasing the mortality rate in the long term.

Pulsatile varicose veins associated with tricuspid regurgitation

Sir

R. L. Blackett and G. E. Heard (*Br J Surg* 1988; **75**: 865) presented two interesting cases of pulsatile varicose veins associated with tricuspid regurgitation. They suggested that it should be possible to exclude an arteriovenous fistula from tricuspid regurgitation in the absence of a characteristic machinery murmur.

We report a similar case where a 69-year-old man, with previous rheumatic fever, developed aortic and mitral valve disease, culminating in Starr–Edwards valve replacement in 1974. He presented to the casualty department with brisk bleeding from left-sided varicose veins which were noted to be grossly pulsatile with an audible continuous bruit overlying the saphenofemoral junction. He had apparently had varicose veins for many years and had been largely asymptomatic apart from some eczema and an early ulcer on his left calf. He was noted to have had cardiac catheterization in 1987 and a presumptive diagnosis of arteriovenous fistula was made. His bleeding having been controlled he was admitted to our unit the following week and it was at this point that an 8 cm jugular venous pressure diastolic murmur at the left sternal edge, pulsatile hepatomegaly to 4 cm and bilateral ankle oedema were noted. He also had less marked right-sided varicose veins which were also pulsatile and had a notable overlying bruit. Although it was probable that tricuspid regurgitation was responsible for this patient's pulsatile varicose veins, it was decided that he would benefit from surgical treatment. He proceeded to exploration of his left groin which revealed no evidence of any arteriovenous fistula, and high saphenous ligation, stripping and multiple excisions were performed.

The points raised by this case are first that it was the presence of a murmur overlying his varicose veins which initially delayed the correct diagnosis. It would appear that although the absence of a murmur may allow the exclusion of an arteriovenous fistula its presence does not allow the exclusion of a cardiac cause. Second, patients with marked venous back pressure are going to develop severe varicose veins with their associated problems if they have high saphenous incompetence and are probably better having these veins treated.

At the time of review this man's leg swelling had considerably reduced, his ulcer had healed and he had symptomatically benefited from having had the procedure performed.

Single duct discharge from the nipple

Sir

In reply to the letter by Chaudray and Fentiman (*Br J Surg* 1988; **75**: 1044) we are interested to read that they consider a haemoglobin-positive discharge requires further investigation by microdochectomy. All the letter lacks is the backing of this fact. We have given the results of an audit of microdochectomy in 170 cases and given our recommendations for management based on this. We would like to see a similar audit by Messrs Chaudray and Fentiman to substantiate their claim, regarding the value of testing for haemoglobin in nipple discharge.

Book reviews

Textbook of Uncommon Cancer

C. J. Williams. 176 × 255 mm. Pp. 1028. Illustrated. 1988. Chichester: John Wiley. £110.00.

The aim of this 1000-page textbook is to 'collect together comprehensive and critical reviews on many of the rare tumours'. It is primarily aimed at the busy clinician, who needs an immediate reference source of more than one or two paragraphs, and a way into the literature.

Dipping into the book to read about my favourite tumours, it seems on the whole remarkably successful. There is a strong clinical bias to most of the chapters, but the opinions are balanced and the references up to date. Rare tumours often provide an opportunity to understand something about biology. Confusing topics like the primitive neuroectodermal tumours are presented clearly and in a way which I think would be helpful to the researcher in neurobiology as well as to the clinician. Many chapters (although not all) include excellent short reviews of aetiology and pathobiology, and even genetics.

The book is well produced: the binding is sturdy, the index works, and the photographs and diagrams are adequately reproduced. I would recommend this as a book for hospital libraries, for the oncology unit, and for the shelves of laboratories where scientists are confused about the difference between a ganglioneuroma and a neuroblastoma.

At £110 this is hardly a book for an individual to purchase, but for a library I think it is good value.

Perspectives in Shock Research

R. F. Bond, H. R. Adams, I. H. Chaudry. 158 × 232 mm. Pp. 431. Illustrated. 1988. New York: A. R. Liss. $90.00.

Attracted by the title, a surgeon might well pick up this book, particularly when he found that it was the report of the proceedings of the Tenth Annual Conference of the American Shock Society and the First International Shock Congress, 1987, sponsored by the Shock Societies of America, Europe and Japan. However, although the contents of this book are much more clinical than those of its nine predecessors, they might surprise the typical surgeon.

He should be interested in the four papers dealing with the Veterans' Administration Cooperative Study No. 209 and the difficulty of trying to decide whether corticosteroids are of therapeutic value in serious sepsis. The overall answer seems to be that they are not but a number of subsidiary questions remain. There is a section of detailed biochemistry on the cellular aspects of shock and on the involvement of the central nervous system, but what of all the papers dealing with the possible roles of eicosanoids, endogenous opioids, complement, activated macrophages and the interleukin family and the whole question of 'mediators'? These are areas of research where the general surgeon seems to play no part and is conspicuous by his absence not only from meetings of this type in North America but from those in Europe as well. The geographical distribution of the abstracts accepted for this Congress in Montreal is of interest: America (North and South), 159; Europe (excepting UK), 34; Japan, 21; China, 6; Middle East, 6; UK, 5. Is the British surgeon right to hold aloof from this field of research? (Some American surgeons would agree with him but their number seems to be falling.) This question is perhaps a reason for reading this book.

Bailey and Love's Short Practice of Surgery. 20th ed.

A. J. Harding Rains and C. V. Mann. 168 × 248 mm. Pp. 1406 + xii. Illustrated. 1988. London: H. K. Lewis. £35.00.

This was the textbook recommended by my surgical teachers both for M. B. surgery and for the final fellowship examination. This is perhaps indicative of my age because I rarely suggest that our present undergraduates purchase such a large and comprehensive book. Most students now rely instead on lecture notes or the excellent *Principles and Practice*.

What of the fellowship candidate? I recently took a straw-poll on the St. Thomas' fellowship course and it was apparent that 'Bailey and Love' is still extremely popular despite the fact that a number of new rivals have recently appeared on the scene.

What then is the secret of this book's phenomenal success? I think this is related to a number of factors, not least of which is its price. If the cost of other large textbooks is taken as a fair guide, then either 'Bailey and Love' is literally being given away, or the publishers of the other books are making an excessive and unjustifiable profit. To some extent the prowess of the book is obviously responsible, because a large print run and guaranteed sales allow a lower profit margin, but this does not seem to be the whole story. Whatever the reason, H. K. Lewis and Company is to be commended on the amazing value of its flagship publication.

Anyway, enough of dull fiscal matters, what of the book? Well, it is still easily recognizable as the infant of its distinguished forebears. There can be little complaint that it retains its title, for when I compared the present 20th edition with my 12th edition, large portions of the text remained unaltered. This is commendable where there has been little in the way of advance, but a textbook rapidly dies when it fails to keep pace with recent developments. There is little to fear on this score in this book; the two main editors have now assembled a large selection of sub-editors or section editors who have ensured that the text is up to date in providing an overview of surgical diagnosis and management in 1988. For example, both extracorporeal shock-wave lithotripsy and balloon angioplasty receive adequate coverage, though I would quibble at the scant attention paid to distal arterial bypass surgery and the place of liver resection in liver neoplasia.

In general the book is slightly uneven, and this reviewer's bias is perhaps revealed if he finds the chapters on arterial disease, venous disease and lymphatic disease the least satisfactory. The orthopaedic section has always been weak, and I found little evidence that this has been rectified in the new edition. I will continue to recommend that fellowship candidates purchase a separate orthopaedic text. In sharp contrast it seemed to me that the chapters devoted to urology were particularly strong.

I have never really liked the presentation or layout of the book and this too remains unchanged, with large tracts of 'small print' and myriads of tiny figures often of indifferent quality. I also must confess to an aversion to the footnotes recording the names of the 'famous' without reference to their published work—as an aside it is interesting to see whose names remain and whose disappear in succeeding editions. How are the mighty fallen!

Despite these criticisms, with which not all will agree, the book will, I am sure, remain a best seller. The tried and trusted formula has always worked until now, though I cannot help feeling that it is time for some radical surgery if the long-term future of this book is to be guaranteed, and it is to continue to outsell all its rivals.

Colour Atlas of Gastrointestinal Pathology

B. C. Morson. 220 × 280 mm. Pp. 290. Illustrated. 1988. Oxford: Oxford University Press. £75.00.

This is a volume in a series known as 'The Oxford Colour Atlases of Pathology'. The series is aimed at the clinical pathologist and postgraduates specializing in pathology.

The book is beautifully produced with almost 600 colour illustrations of both excised surgical specimens and histopathological appearances. The photographs are clear and remarkably well reproduced. Each illustration has a well written explanatory legend. As is appropriate in an atlas, about 80 per cent of the contents is occupied by the illustrations and their legends. Interposed between each group of illustrations are short areas of text which introduce each topic. The book confines itself to the diseases from the oesophagus to the anus but does not include diseases of the associated organs such as liver or pancreas.

Anyone interested in gastrointestinal pathology will enjoy dipping into this book. I believe it will be a useful reference work in many pathology departments.

Femoro-popliteal Bypass: Can Better Assessment Lead to Improved Results?
Leicester, UK
Information: Miss Rosalind Aldwinckle, Secretary to Professor P. R. Bell, University of Leicester School of Medicine, Department of Surgery, Clinical Sciences Building, The Leicester Royal Infirmary, PO Box 65, Leicester LE2 7LX, UK

25–26 February 1989
Second Annual Congress on the North American Society of Phlebology
New Orleans, USA
Information: Pat Curl, Course Coordinator, North American Society of Phlebology, 3960 Park Boulevard, Suite E, San Diego, California 92103, USA

4–11 March 1989
7th Winter Congress: Diagnostic Imaging
Courchevelle, France
Information: Ms Mary Ullman, Winter Congress, 21915 Roscoe Boulevard, Suite 222, Canoga Park, California 91304, USA

5–7 March 1989
Surgical Masterclass for Consultants and Senior Registrars in General Surgery
Aviemore, U.K.
Information: Clerk to the College, The Royal College of Surgeons of Edinburgh, Nicolson Street, Edinburgh EH8 9DW, UK

5–10 March 1989
Magnetic Resonance Imaging Update 1989: Winter Conference
Snowbird, Utah, USA
Information: Radiology Postgraduate Education, Room C324, University of California, San Francisco, California 94143-0628, USA

11–18 March 1989
7th Cardiosurgical Symposium in Zurs
Zurs, Austria
Information: Professor Dr M. Deutsch, Abtlg fur Herz-Gefass und Thoraxchirurgie, Krankenhaus der Barmherzigen, Schwestern vom Heiligen Kreuz, Grieskirchner Strasse 42, A 4600 Wels, Austria

12–15 March 1989
Current Problems in Breast Cancer
Vienna, Austria
Information: Secretariat ICS, Elisabeth Ribar-Maurer, c/o Wiener Medizinische Akademie, Alser Strasse 4, A 1090 Vienna, Austria

27–31 March 1989
Neuroradiology at Vail
Vail, Colorado, USA
Information: Janice Ford or Nancy Fedullo, Department of Radiology, Hospital of the University of Pennsylvania, 3400 Spruce Street, Philadelphia, PA 19104, USA

29–31 March 1989
Annual Meeting of the Association of Surgeons of Great Britain and Ireland
Edinburgh, UK
Information: The Honorary Secretary, Association of Surgeons of Great Britain and Ireland, 35/43 Lincoln's Inn Fields, London WC2A 3PN, UK

6–9 April 1989
4th ASEAN Otorhinolaryngological Head and Neck Congress
Singapore
Information: Dr R. E. Stanley, Organizing Secretary, c/o ENT Department, Singapore General Hospital, Singapore 0316

22–28 April 1989
Critical Care in the 1990s
Aruba, Dutch Caribbean
Information: Dr Omar Prakash, Thorax Centre, Erasmus University, PO Box 1738, DR Rotterdam, The Netherlands

24–27 May 1989
8th Annual Meeting of the American Association for Cancer Research
San Francisco, California, USA
Information: American Association for Cancer Research, 530 Walnut Street, 10th Floor, Philadelphia, Pennsylvania 19106, USA

4–17 June 1989
Methods of Immunologic Research and Diagnosis
Buffalo, New York, USA
Information: Dr J. F. Mohn, Director, The Ernest Witebsky Center for Immunology, 272 Sherman Hall, Buffalo, New York 13214, USA

Relied upon by leading surgeons, Swann-Morton blades are as worldwide as their reputation for quality. Alongside their classic surgical range, there are the "Major" orthopaedic blades, "Minor" disposables, and special blades for cervical biopsy and myringotomy. Most recent is the completely new "Fine" range. Extensively researched, all blades are produced under strict quality control by precise automation, and inspected at every stage.

Swann-Morton always have the blade for the task, uniformly correct in shape, size and weight, and durably sharp–that's why they are World-Famous!

Swann-Morton Limited, Penn Works,
Owlerton Green, Sheffield S6 2BJ, England.

PIPRIL

INTRAMUSCULAR/INTRAVENOUS PIPERACILLIN

Still a key move in surgical infections

- Proven single agent activity[1-3]
- Broad spectrum cover, including anaerobes.[4] Active against *Strep. faecalis*[5] – unlike cephalosporins, aminoglycosides and metronidazole.
- Highly synergistic with aminoglycosides[6,7]
- Low potential for inducible resistance compared with 'third generation' cephalosporins[8,12]
- Effective concentrations in bile and peritoneal fluid[9,10]
- Well tolerated[11]

Prescribing Information. **Indications:** Pipril is a broad spectrum bactericidal penicillin for the treatment and peri-operative prophylaxis of systemic or local infections caused by sensitive organisms. **Dosage:** Adult patients with normal renal function should receive 4-8g daily in divided doses for mild or uncomplicated infections. In serious or life-threatening infections 12-16g daily in divided doses. For peri-operative prophylaxis 2g just prior to surgery followed by at least two doses of 2g at four or six hour intervals. Patients with renal insufficiency may need dosage reduction – see Data Sheet. Children 2 months to 12 years of age: 100-300 mg/kg daily in three to four divided doses. Neonates and infants under two months of age: 100-300 mg/kg daily in two equally divided doses. **Contra-indications:** Penicillin or severe cephalosporin hypersensitivity. **Precautions:** Safety for use in pregnant or lactating women has not yet been established. **Side effects:** Uncommon and typical of injectable penicillins. **Administration:** Pipril is presented as 1g or 2g vials, 4g infusion bottles and 4g infusion packs containing piperacillin as piperacillin sodium. See Data Sheet or package leaflet for full details of preparation and administration. **Product Licence No.** 0095/0073. **Basic NHS Price:** 1g vial £2.98, 2g vial £5.90, 4g infusion bottle £11.66. 4g infusion pack (4g bottle, 50 ml WFI plus needle) £12.43. Further information is available on request.

Instructions to authors

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another Journal, has not been accepted for publication elsewhere and has not already been published. Articles and their illustrations become the property of the Journal unless rights are reserved before publication. The title should indicate if the paper is based on a previous communication to a society or other meeting. Authors are requested to send three copies (one of which must be the top copy) of original articles and other editorial matter to: *The Editor, c/o Lynne Ponjee, The Editorial Secretary, Butterworth Scientific Ltd., PO Box 63, Westbury House, Bury Street, Guildford, Surrey GU2 5BH, UK. Telephone number: 0483 301439.*

A covering letter must be signed by all authors and must state: if an abstract of the work has been published; and whether the manuscript and/or illustrations are to be returned. Books for review should also be sent to this address.

The first named author is responsible for ensuring that any other authors have seen and approved the manuscript and are fully conversant with its contents.

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. When quoting specific materials, equipment and proprietary drugs, authors must acknowledge the manufacturer but generic names should normally be used.

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *British Medical Journal* 1988; **296**: 401–5 or the *Annals of Internal Medicine* 1988; **108**: 258–65 or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from the Editor, British Medical Journal, BMA House, Tavistock Square, London WC1H 9JR (enclose 50p).

Typescripts

Papers should be typewritten on A4 paper (210 × 297 mm) with double spacing and 4 cm margins. Each of the following sections should begin on a new page: title page, summary, text, acknowledgements, references, tables, legends for illustrations.

Title page

The title page should give: (1) title of the article; (2) names and initials of each author with their highest academic qualifications; (3) the department and institution to which the work should be attributed; (4) name and address of author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; (6) keywords.

Summary

The second page of the manuscript should carry a summary of not more than 150 words. It should embody the purposes of the study or investigation, basic procedures (study material and observational and analytic methods), main findings (with specific data and their statistical significance, if possible) and the principal conclusions.

Tables and illustrations

Each table with an appropriately brief title should be typed on a separate page. Illustrations (line drawings, radiographs, photomicrographs etc.) should be submitted in the form of glossy prints, original transparencies, or negatives and should not be mounted. Each illustration should have a label pasted on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); the top of the illustration should be indicated. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Explanations of symbols and shading used should appear in the legend. Survival curves should be accompanied by a table giving the actual numbers involved. The legends to illustrations and the footnotes to tables should contain brief but comprehensive explanations of the information contained therein. Prospective authors are strongly advised to refer to recent issues of the Journal for examples of accepted layout. Three copies of all illustrations should be submitted. A contribution towards the cost of colour reproduction is usually requested. If a table or an illustration has been reproduced from a published work the original source thereof must be given in full, permission having been granted by the author and by the publisher.

Text

The text should usually (but not exclusively) be organized into: introduction, patients/materials and methods, results, discussion.

Abbreviations

Authors should limit the use of abbreviations. Terms which are mentioned frequently may be abbreviated but only if this does not detract from reader comprehension. Abbreviations should be used consistently throughout the text but must be clearly defined.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethical committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached.

Numbers and units

The decimal point, not a comma, is used, i.e. 5·7. A space and not a comma follows thousands and multiples thereof, ie, 10 000. SI units (International system of units) are to be used except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, the actual values and units should be given, with SI equivalents inserted in parentheses at appropriate points.

Statistics

Any statistical methods used should be specified in the methods section, and any not in common usage should be supported by references. For detailed guidance, authors should consult the *British Medical Journal* 1983; **286**: 1489–93.

References

In the text, references should be numbered consecutively by superscript: 1,2 or 1–3. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation quoted) and year of publication, volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; 66: 184–6. The sequence for the chapters of a book should be: author(s), chapter title, edition, book title, place of publication, publisher, year of publication, page numbers, for example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In :Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications.* New York: Springer-Verlag 1981: 123–63.

Radiotherapy Titles from Butterworths

Megavoltage Radiotherapy 1937–1987

(BJR Supplement No 22)

Editors **P N Plowman** and **A N Harnett** Both at St Bartholomew's Hospital, London, UK

Megavoltage Radiotherapy 1937–1987 is the proceedings of a conference held to mark the 50th anniversary of megavoltage radiotherapy at St Batholomew's Hospital and contains 15 full papers from invited speakers and over 100 abstracts. It is a significant reference work on current practice in radiotherapy, whilst offering insights on future trends as well – a vital publication for clinicians and all those involved in cancer management.

Contents: Introduction • Opening plenary section • Precision in radiotherapy • CNS tolerance and clinical results • Abdominal organ tolerance and radiotherapy • Current status of electron therapy – clinical and physical aspects • Paediatric radiotherapy • Breast conservation • Interstitial radiotherapy • Current concepts in fractionation • Response predictors in radiotherapy • Quality assurance in radiotherapy • Xenografts and the radiobiology of human tumours • Ocular radiotherapy • Total body irradiation • Poster presentations • Index to authors

NEW FROM BUTTERWORTHS

MANAGEMENT OF ABDOMINAL HERNIAS

H Brendan Devlin MA MD MCh (Dublin) FRCS(England) FRCS(Ireland) FACS
Consultant Surgeon, North Tees General Hospital, Stockton-on-Tees, Cleveland, UK

Management of Abdominal Hernias is the most comprehensive work to date on the subject. In this exhaustive volume the author discusses the historical background to hernia management and its influence on current practice.

The basic sciences and operative technique of hernia surgery are dealt with in practical terms and guidance on complications and postoperative care is supported by new data based on long term studies.

- ★ **the author is a leading authority on hernia management**
- ★ **extensively illustrated with high quality line drawings, half-tones and colour photographs.**

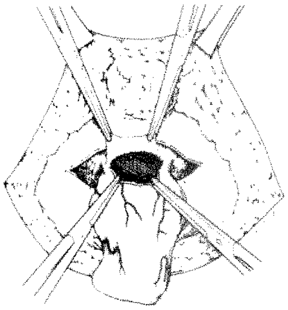
"This book is beautifully produced, clearly written and profusely illustrated, mainly by excellent line drawings. It would be of considerable value to the surgeon in training (who, in this country, is called upon to do the majority of this type of surgery) but it would also be read with interest by his Chief."

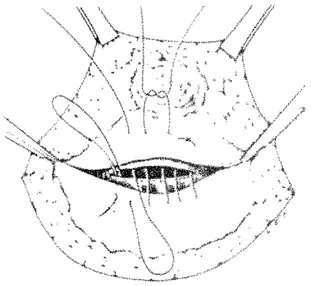
British Journal of Surgical Practice

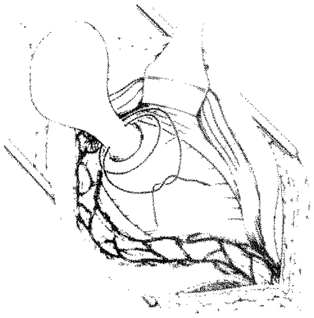
"The anatomy of the abdominal wall is excellently set out and clearly described and I would recommend all surgeons in training, particularly at senior house officer level, to read it.

"This is a very readable and enjoyable book. It is not directed at any particular grade of surgeon but will inform and enlighten the majority of those who read it."

British Journal of Hospital Medicine







Concise contents: Preface · General introduction and history of hernia surgery · Essential anatomy of the abdominal wall · Epidemiology and aetiology of primary hernias in adults · Logistics and economics of hernia repair · Principles in hernia surgery · Anaesthesia · Complications of hernia in general · Groin hernias in babies and children · Umbilical hernia: operation in babies and children · Diagnosis of a lump in the groin in the adult · Inguinal hernia in adults · Femoral hernia · Extraperitoneal or preperitoneal repair of groin hernias using prosthetic reinforcement · Umbilical hernia in adults · Epigastric hernia · Obturator hernia, lumbar hernia, sciatic hernia, supravesical hernia · Spigelian hernia · Incisional hernia (excluding parastomal hernia) · Parastomal hernia · Complications of hernia repair · Epilogue and general conclusions · Biographical notes · References and further reading · Index

March 1988 222 pages 276 x 219 mm Hardcover Illustrated – 11 half tones and 267 line drawings 0 407 00348 7 £60.00

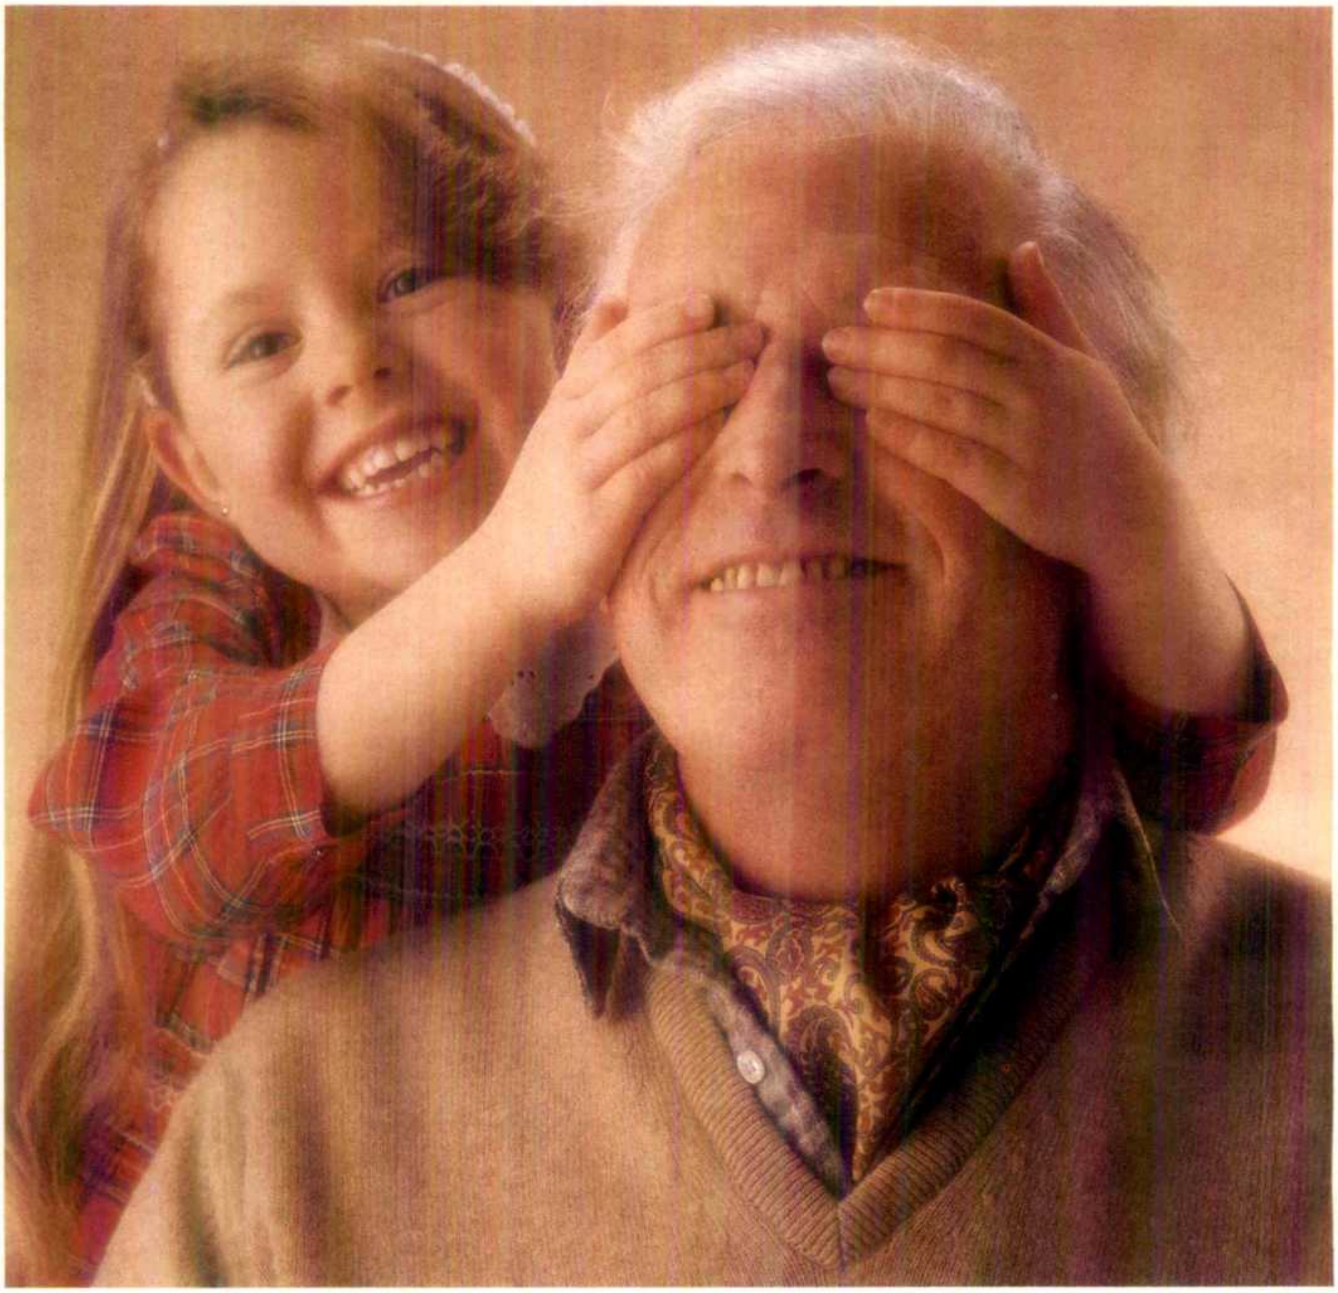
Butterworths
meeting professional needs.

Guess which prostate cancer treatment most patients would choose.



In a recent study[1], 57 prostate cancer patients were invited to participate in choosing their treatment. All were informed that the two treatments available, sub-capsular orchidectomy or 'Zoladex', were similar in efficacy and side effects. 49 of the patients (86%) opted for 'Zoladex'.

A recent trial[2] has established the equivalence of 'Zoladex' to orchidectomy.

Zoladex

goserelin

Effective therapy without surgery.

▼ 'ZOLADEX' PRESCRIBING NOTES.

Use: Prostate cancer suitable for hormonal manipulation. **Presentation:** A sterile depot containing goserelin 3.6mg. **Dosage and administration:** One depot injected subcutaneously into the anterior abdominal wall every 28 days. **Precautions:** Care with patients at particular risk of developing ureteric obstruction or spinal cord compression. Consider initial use of an anti-androgen at the start of therapy. **Side effects:** Hot flushes, decrease in libido and occasional breast swelling and tenderness. Skin rashes (generally mild). Occasional mild bruising at injection site. Initial transient increase in serum testosterone may cause temporary increase in bone pain. **Product licence number:** 29/0198. **Basic NHS Price:** £114.00 per depot. 'Zoladex' is a trademark. Further information is available from: ICI Pharmaceuticals (UK), Southbank, Alderley Park, Macclesfield, Cheshire SK10 4TF.

Editorial process at The British Journal of Surgery

Now that I am no longer responsible for *The British Journal of Surgery* policy and have seen a new management take over, I feel it might be helpful for readers and potential, or even experienced, authors to know how we have run the Journal over the past years—a pattern that will probably persist at least for the moment.

First I should make it absolutely clear that the Editors are completely independent. There is an Editorial Committee but its work is largely related to overall policy and financial matters. The Editorial Committee also maintains a healthy interest in the sales of the Journal, so providing a goad to the publishers. Beyond this, the Chairman and his committee vest all day-to-day decisions in the Editors and are there to back them up if problems occur.

These things having been established, how is an individual paper dealt with? When a paper reaches the Editorial Office it is allocated a number for identification purposes which follows it through the rest of its editorial life or death. An editorial decision is then taken about whether or not it should be subject to peer review. At this stage the Editors are entitled to say if the paper is in no way suitable for the Journal; they do this rarely and sometimes I wish that they would more often follow the *Lancet*'s policy of making radical and arbitrary judgements. However, editors are usually cautious people and I cannot blame them for sending most of the papers, in the increasingly specialized fields of surgery, out to referees.

The process of 'peer review' has been debated endlessly and is superbly reviewed by Stephen Lock in his Rock Carling lecture[1]. This instrument is fallible but it is the best we have. Nevertheless it can be made more realistic (if not more precise) by two manoeuvres, both of which are part of the editorial process at *The British Journal of Surgery* . First we send the manuscript to two independent referees; this may give the Editors two biased views. Of more significance is the fact that we send each referee's observations to his opposite number, so discouraging him from careless or outrageous statements that might offend his colleague. Second, we insist that the referee's report should be couched in terms that can be transmitted to the author. We have no objective data about the effect of these measures but we feel that both tend to make the referee more responsible and accountable. Certainly I personally have found that the knowledge that my observations will be transmitted both to my peer colleague and to the authors has concentrated my mind. Furthermore, it has made me refrain from making outright scurrilous criticism, though it has also inhibited the free flow of my invective in a way that I sometimes regret. The two referees' reports are then returned to the Editors. Usually the referees agree and the concordance rate over whether to publish or not is around 60 per cent. The editors are then faced with making a value judgement which embraces at least three things. Is the paper a real contribution to the science and practice of surgery? If so, it ought to be published. Given this, is there room for the paper in the Journal, which is restricted to a certain size by the economics of publishing? Finally, if neither of the preceding criteria apply, how can the Editor best tell the author(s) that the work is at present not suitable for publication in the Journal? There is a difficult balance on the one hand between saying outright that the work is bad and on the other hand that it is not suitable for the audience that the Editors feel is 'out there' waiting for the next issue of the Journal. Here there are no decision rules to choose decision rules.

Going back to the distinction between what is publishable and what can be published, it is often confusing for authors to receive an encouraging referee's report and at the same time a rejection from the editor. Could I just emphasize that journals cannot lose money if they are to survive; in consequence there is a fine balance between the production costs, the advertising revenue, the subscription base and the size of the Journal in terms of editorial pages. We always wish to expand but the laws of the market-place govern our ability to do so.

Given that a paper has survived all these hurdles, there is yet the matter of sub-editing. Few authors seem to realize that their manuscript is often riddled with spelling errors, grammatical infelicities and flights of fancy that fly in the face of logic and clear exposition. Referees often help us in this task (and I have had my own

0007-1323/89/030211-02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

seemingly pellucid writing savaged and salvaged quite justifiably in this way), but there remains a burden on the editorial staff which often results in a final form of which the authors are proud even though they owe it all to hidden editing. There are two components to this sub-editorial task. Firstly, making sure that there are no professional uncertainties; here we must rely, for the most part, on our referees, but from time to time members of the Editorial Committee (including the Chairman) are asked to make a final Solomonic judgement. Secondly, there is the tedious business of checking references and referring back to the author(s) over obscure matters and minor points. The Editorial Office finds itself doing a great deal of chasing after missing items of information which could be reduced if authors were more careful with their manuscripts. There is also the possibility of being chased by indignant authors who feel that they are not getting a square deal, but thankfully this is uncommon.

Once a paper is through this phase there remains the delay between acceptance in principle, acceptance in fact (when all errors and problems are eliminated), and publication time. The last is determined by the following: pressures of priority—a new and unique observation is likely to be published ahead of more mundane matters (as viewed by the Editors of course); the desire to associate papers on a similar or related subject, so building up an issue of the Journal that is seen to represent a theme; and the parallel aims that the Journal must pursue. Among the latter are the publication of the Abstracts of the Surgical Research Society, a special issue for the Association of Surgeons, and the legitimate demands of a vigorous correspondence column.

Thought must be spared, therefore, for the difficult task the Editors and the Editorial Committee have in order to meet these diverse needs. *The British Journal of Surgery* is here to serve surgery in general and British surgery in particular. If its balancing act does not please everyone all the time, this is because the task is so complex.

Intrahepatic stones

In an article entitled 'Common Duct Stones of Liver Origin'[1], Digby drew attention to the common occurrence of stone formation in the intrahepatic bile ducts among the Hong Kong Chinese. It is now a recognized disease entity with the highest incidence found in Taiwan, Hong Kong and the southern part of China, followed by Japan, Korea and Singapore. In Taiwan, where the incidence is the highest, 30 per cent of all patients suffering from gallstone disease have intrahepatic stones[2].

Intrahepatic stones are in the most part made of calcium bilirubinate. Stones are formed as a result of infection of the intrahepatic ducts by enteric bacteria, many species of which produce a large amount of the enzyme β-glucuronidase. The enzyme deconjugates bilirubin diglucuronide in the bile. The deconjugated bilirubin combines with calcium ions to form insoluble calcium bilirubinate[3]. Based on the similarity between the bacteria found in the intrahepatic stones and the gut flora, the source of the bacteria is probably the gut. The route of transmission is uncertain, and it is not known whether the bile ducts or the liver of patients suffering from this disease have a lower resistance to bacterial colonization.

Patients usually present with symptoms of cholangitis, namely fever, right upper quadrant tenderness and jaundice. The symptoms may be mild and non-specific or severe, with mental confusion and shock. After preliminary blood tests to confirm the presence of infection and obstructive jaundice, ultrasonography of the liver and the gallbladder is performed. In expert hands, 90 per cent of the intrahepatic stones can be detected by ultrasound. If the diagnosis is confirmed or strongly suspected on clinical grounds, conservative treatment, consisting of nothing by mouth, intravenous fluids and antibiotics, is started.

A better knowledge of the bacterial flora involved and the availability of potent antibiotics in the last few years have greatly improved the outcome for patients with intrahepatic stones. In the past, up to 50 per cent of patients did not respond to conservative treatment and had to be operated on as emergencies. Emergency operations carried a high risk of mortality (15 per cent). Furthermore, because of the precarious condition of the patients, the operative procedures were temporizing and frequently inadequate. Even if the patients' vital signs were stable during the operation, surgeons were frequently unable to perform definitive procedures because of insufficient knowledge of the location of stones and the presence of biliary strictures. Thus, with few exceptions, patients undergoing emergency operations had retained stones or unrelieved strictures or both. Before the development of postoperative choledochoscopy, some patients with retained stones and strictures were subjected to second operations while others were left untreated. Because of this, the incidence of recurrent symptoms was high.

Today, less than 15 per cent of patients require urgent intervention owing to antibiotic treatment failure. The patients who recover undergo thorough investigations including repeated ultrasonography, endoscopic retrograde cholangiopancreatography (ERCP) and occasionally both ERCP and percutaneous transhepatic cholangiography. The surgeon, armed with complete information about the biliary system, is then able to plan and perform more definitive operations.

A definitive operation starts with a routine common bile duct exploration, during which flexible choledochoscopy is performed. All the segmental bile ducts are examined. The sites of stones and strictures as shown by preoperative studies are confirmed. If the stones and strictures are localized to a segment or lobe of the liver and the involved part of the liver is atrophic, liver resection is performed[4]. In this setting, operative mortality of liver resection is only 2 per cent and the long-term results are excellent. If liver resection is not indicated, stone forceps and irrigation are first used to extract easily removable stones. Further stones are retrieved with wire baskets and biliary balloon catheters under choledochoscopic guidance[5]. Large stones impacted in the right or left hepatic ducts or at their confluence are removed by extending the choledochotomy into the hepatic ducts. Large stones in the segmental ducts are first broken up with electrohydraulic shock waves. The electrode can be introduced through the working channel of the flexible choledochoscope, taking care to extend the tip at least 1·5 cm beyond the choledochoscope. The fragments are then either flushed out or removed with basket retrievers. Occasionally, it is not possible to remove all stones because of their large number and peripheral location[5]. Some stones may be left behind to be removed by postoperative flexible choledochoscopy[6].

0007-1323/89/030213-02$3.00 © 1989 Butterworth & Co (Publishers) Ltd

Treatment of biliary strictures requires preoperative identification and planning. Strictures associated with intrahepatic stones can be found intrahepatically or extrahepatically. Extrahepatic strictures are treated by sphincteroplasties if they are located in the ampullary region. Higher extrahepatic strictures are treated by hepaticojejunostomies. Intrahepatic strictures are treated by biliary–enteric anastomosis to segmental bile ducts. The left hepatic duct is most frequently involved. Bypass using the segment III duct and the round ligamental approach[7] is the best treatment for left hepatic duct strictures. Stones can be removed directly from the dilated segmental ducts when they are opened for biliary–enteric anastomosis. Occasionally, intrahepatic strictures are diaphragm-like, and are located close to the right and left hepatic duct confluence. In these cases, the strictures are exposed by extending the choledochotomy. The diaphragms are partially excised and the ducts are reconstructed by a procedure similar to the sphincteroplasty used for widening the sphincter of Oddi.

Postoperative flexible choledochoscopy is used to remove any stones which are left behind or missed at operation. This procedure is performed via the T tube tract about 6 weeks postoperatively. About 85 per cent of the intrahepatic stones shown by postoperative cholangiography can be successfully removed[6]. With such advances in stone retrieval techniques, the ultimate retained stone rate has been reduced from approximately 50 per cent to about 5 per cent. The reduced incidence of retained stones combined with adequate relief of biliary strictures should reduce the rate of recurrent symptoms, which amounts to about 25 per cent over 5 years[8]. In our preliminary review of patients treated recently, the symptomatic recurrence rate is reduced to about 5 per cent; however, the median follow-up is still short (2 years) and long-term results are awaited.

Several controversial points concerning the treatment of intrahepatic stones remain to be settled. Intrahepatic stones have been removed by non-operative procedures and, among them, percutaneous transhepatic choledochoscopy (PTCS) is the most successful. Whether this should be done instead of surgery is not clear at present. As about 35 per cent of the patients with intrahepatic stones also have significant strictures in major bile ducts, and 40 per cent also have gallbladder stones, it would appear that PTCS is not suitable for the majority of patients. Another unanswered question is whether emergency surgery or endoscopic papillotomy combined with nasobiliary drainage should be performed in patients who do not respond to conservative treatment. The latter approach is preferred if it is effective in relieving biliary obstruction and infection caused by intrahepatic stones as it will allow patients to undergo operation in safer circumstances and after proper investigation. Many stone dissolution and fragmentation techniques have also been developed and applied to intrahepatic stones. Ethylenediaminetetra-acetic acid dissolution, and laser or ultrasound fragmentation are some examples. Which technique is superior and which should be used in a given situation are areas which deserve further study.

Mortality and perforated peptic ulcer: a case for risk stratification in elderly patients

In a consecutive series of 284 patients with a perforated peptic ulcer (229 pyloroduodenal, 55 gastric) there was a 26 per cent hospital mortality rate, and patients aged ⩾70 years ($n=176$) *had a significantly higher mortality rate (34 per cent) than patients aged <70 years (14 per cent,* $P<0{\cdot}001$*). Multiple clinical variables were significantly more common in the elderly group of patients (65 per cent), in those having non-steroidal anti-inflammatory drugs or steroid therapy (56 per cent), in patients where there is an absence of a previous dyspeptic history (69 per cent), and when risk factors such as delayed presentation (33 per cent) and the presence of shock on admission to hospital (27 per cent) are present. Definitive operations (vagotomy or gastrectomy) had an increased mortality rate in the elderly* ($P=0{\cdot}018$)*. Risk scores based upon the presence of shock, delayed presentation or concurrent medical illness could have predicted 87 per cent of postoperative deaths in elderly subjects, and it is suggested that risk stratification and greater caution in the use of definitive operations for perforated ulcer may result in a reduction in the high mortality rate in elderly subjects.*

There has been a dramatic reduction in the incidence of elective operations for chronic peptic ulceration during the last decade following the introduction of the H_2-receptor antagonist drugs[1–4]. There has also been a reduction in the incidence of perforated peptic ulcer[5] but there is reason to believe that the mortality rate as a result of this complication may be increasing. Many perforations occur in elderly subjects with acute rather than chronic peptic ulcers and mortality rates of 18–48 per cent have been reported[5–7].

We have reviewed our recent experience of 284 consecutive patients with a perforated peptic ulcer, with particular reference to the factors determining the outcome in elderly subjects.

Patients and methods

The case records of 284 patients with a perforated peptic ulcer admitted to the surgical units of the Royal Devon and Exeter Hospital during the period 1979–86 were reviewed. The patients were admitted under the care of five consultant surgeons and the diagnosis was confirmed by operation in 265 patients, by radiology in three and at autopsy in 16. The study included an analysis of the clinical features of the patients on admission, the incidence of adverse prognostic or risk factors[8,9], the methods of surgical treatment, the causes of death, and the 30-day hospital mortality rate. For the purpose of the study the patients were divided into two groups according to their age at presentation: a group of 176 patients aged ⩾70 years, and a group of 108 patients aged <70 years.

The risk factors or adverse prognostic factors examined in this study were based on the criteria of Boey *et al.*[9] and included the presence of shock on admission to hospital (a documented systolic blood pressure <100 mmHg), delayed presentation (>24 h after perforation), and serious concurrent medical illness. In most cases the medical illnesses had required previous attendance at hospital on at least one occasion, and they included major chronic cardiovascular or respiratory disease, diabetes, renal failure, hepatic insufficiency, and various types of disseminated malignancy.

The results were subjected to statistical analysis using the χ^2 test and Fisher's exact test.

Results

The majority of patients were elderly. The average age was 70 years (range 19–98), and the male:female ratio was 1:1·1. Pyloroduodenal ulcers occurred in 229 patients (81 per cent) and gastric ulcers in 55 (19 per cent). A previous dyspeptic history >3 months was elicited in 109 patients (38 per cent), and 124 patients (44 per cent) were receiving either non-steroidal anti-inflammatory drugs (NSAIDs) or systemic corticosteroids. Shock, delayed presentation, and concurrent medical illness occurred in 21, 26, and 30 per cent of cases respectively.

Clinical features of the two groups of patients (Table 1)

The average age of the elderly group of patients was 80 years compared with an average age of 55 years in the group aged <70

years, and the elderly group included a significantly higher proportion of women, patients receiving treatment with NSAIDs or steroids ($P<0.001$), and a significantly higher incidence of risk factors such as shock ($P<0.01$) and delayed presentation ($P<0.001$).

Risk scores were calculated for the two groups based on the presence of shock, delayed presentation or concurrent medical illness, and the elderly group had a significantly higher incidence of positive risk scores ($P<0.001$).

Methods of treatment (Table 2)

Nine patients (all aged ≥70 years) were moribund on admission to hospital and died within a few hours. Ten patients were treated conservatively: in three cases (two ≥70 years, one <70 years) because they were judged to have a localized perforation, and in seven cases (three ≥70 years, four <70 years) because they were judged to be unfit for any surgical procedure.

Simple suture of the perforation with an omental patch was performed in 28 per cent, and there was a slightly higher incidence of suture operations in the elderly. All patients received H_2-receptor antagonists after these procedures, and 16 patients with gastric ulcers treated by suture either had a biopsy or excision of the ulcer for histological confirmation of peptic aetiology.

More than 70 per cent of perforations were treated by a definitive procedure, usually a truncal vagotomy and drainage procedure, and there was a significantly higher incidence of definitive procedures in patients aged <70 years ($P<0.05$).

The operations were performed by five consultant surgeons and junior staff of registrar or senior registrar status. Ninety per cent of the operations were performed by the junior staff, and there was a similar distribution of junior and senior surgeons involved in the treatment of both groups of patients. Only 13 per cent of the operations were performed during the night (midnight–09.00 hours), and the highest proportion (44 per cent) occurred in the evening (17.00–24.00 hours).

Mortality (Tables 3 *and* 4)

The overall hospital mortality rate was 26 per cent, and 58 postoperative deaths resulted in a perioperative mortality rate of 22 per cent. Seven of the ten patients treated conservatively failed to survive.

The mortality from perforated peptic ulcer was clearly age-related (*Figure 1*), and there was a significantly higher mortality rate in patients aged ≥ 70 years (34 per cent overall, and 29 per cent postoperatively). Comparison of the two groups of patients (*Table 3*) revealed a significantly higher mortality rate after simple suture compared with definitive procedures (vagotomy or gastrectomy) in both groups but patients aged ≥70 years had a significantly higher mortality rate after definitive operations than those aged <70 years ($P=0.018$): definitive procedures in patients aged <70 years resulted in a mortality rate of only 3 per cent. The higher mortality rate in the elderly occurred irrespective of ulcer type although there was a particularly high rate (41 per cent) after operations for gastric ulcer.

The majority of deaths after ulcer surgery were related to coexisting cardiovascular or chronic respiratory diseases (*Table 4*) but there was a high incidence of fatal pulmonary embolism in the elderly (6 per cent after simple suture and 2 per cent after definitive operations), and a 6 per cent incidence

Table 4 *Causes of death after simple suture or definitive procedures (vagotomy or gastrectomy) in the two groups of patients*

Figures in parentheses are percentages. * $P<0\cdot001$, † $P<0\cdot05$: shock and medical illness significantly related to mortality rate in patients aged ≥70 years; ‡ $P<0\cdot001$: medical illness significantly related to mortality rate in patients aged <70 years

of potentially avoidable fatal complications after definitive operations in this group, including burst abdomen and disruption of gastrointestinal suture lines.

The majority of deaths and complications were related to the large number of operations performed by surgeons in training, but the mortality rate (20 per cent) was actually slightly less than that encountered by consultant surgeons (24 per cent). However, a higher proportion of the consultant operations were definitive procedures for perforated gastric ulcers.

Risk factors (Table 5)

The association between risk factors and mortality has been studied only in the 265 patients who were judged to be candidates for a surgical operation. Moribund patients and those considered totally unfit for a general anaesthetic have been excluded from the analysis.

The presence of shock on admission (systolic pressure <100 mmHg) and concurrent medical illness were significant independent prognostic factors in patients aged ≥70 years but only concurrent medical illness was significantly related to the mortality in patients aged <70 years. Delayed presentation (>24 h) was not a significant independent prognostic factor in either group. Certain risk factors (concurrent medical illness and delayed presentation) were significantly more common in patients treated by simple suture ($P<0\cdot01$), and this factor may account for the higher mortality rate after suture operations.

Risk scores had significant value in the prediction of perioperative mortality, and a scoring system utilizing three prognostic variables (shock, delayed presentation, and concurrent medical illness) had greater sensitivity than a system based on two factors (shock and medical illness). The three-factor system predicted 41 of 47 deaths in patients aged ≥70 years (87 per cent sensitivity) and 9 of 11 deaths in patients aged <70 years (82 per cent sensitivity). However, the system had rather less specificity (41 per cent in patients aged ≥70 years and 74 per cent in patients aged <70 years). The two-factor system had a 74 per cent sensitivity and 60 per cent specificity in patients aged ≥70 years, and a 64 per cent sensitivity and 77 per cent specificity in patients aged <70 years.

Discussion

In a review of perforated duodenal ulcer 10 years ago, Johnston[10] stated that there was an average perioperative mortality rate of 7 per cent, and he made a plea for the greater use of definitive operations in selected patients with chronic ulcers. However, there is evidence that the epidemiology and mortality rate in patients with perforated peptic ulcer are changing. In a review[5] of perforated ulcers (duodenal and gastric) presenting in Oxford, UK during the period 1965–82 it was found that the average age of men with duodenal ulcer was increasing (59 years in the period 1977–82), that there was an increasing incidence of perforation in women, and that the majority of the patients had acute ulcers. The overall mortality rate for the period 1977–82 was 13 per cent but patients aged >70 years had a mortality rate of 30 per cent. Other reviews of perforated peptic ulcer in the USA[7] and in the UK[6] have reported mortality rates of 18–48 per cent in the elderly.

In the present study the average age of the patients was 70 years, and the overall mortality rate was 26 per cent. The mortality was clearly age-related: patients aged ≥70 years had a mortality rate of 34 per cent, and in those aged <70 years it was 14 per cent. Studies of the group aged ≥70 years showed that the majority of patients were women, more than half were receiving NSAIDs or systemic steroids, and few (31 per cent) had any significant dyspeptic history.

It is perhaps surprising, therefore, that the majority of patients had a definitive operation, usually a vagotomy and pyloroplasty for pyloroduodenal perforation. It is not possible in this retrospective analysis to elicit the factors that determined the choice of operation in most cases, although it appears that the use of definitive surgery was governed by the appearance of the ulcer at operation rather than by the dyspeptic history.

Retrospective studies of the clinical variables which may be associated with the mortality of perforated peptic ulcer have suggested that the risk factors include shock, advanced age, delayed presentation, and significant peritoneal contamination[11–14]. However, in a prospective study of perforated duodenal ulcers presenting in Hong Kong, Boey *et al.*[8] found that the risk factors which had independent significance in relation to perioperative mortality were preoperative shock (blood pressure <100 mmHg), concurrent medical illness, and long-standing perforation (delayed presentation). The significance of these risk factors was validated in a second prospective study[9] and it was possible to predict the mortality risk in patients undergoing surgery by stratification of the risk factors. A scoring system utilizing preoperative shock (blood pressure <100 mmHg), concurrent medical illness, and delayed presentation (>24 h) had 100 per cent sensitivity and a false-positive error rate of 50 per cent. Patients with one, two, or three risk factors had mortality rates of 10, 46, and 100 per cent respectively. On the basis of these findings the authors suggested that risk stratification should be used in the selection of patients for definitive duodenal ulcer surgery, and that such operations should be performed only in good-risk patients.

We have examined the same risk factors in this retrospective analysis of perforated peptic ulcer in Exeter. The patients are by no means comparable with those studied in Hong Kong[9] where the average age was 51 years and the male:female ratio was 3·6:1. Moreover, the Hong Kong study excluded patients with gastric ulcers. These factors and the inevitable limitations of a retrospective analysis may explain some of the differences in the results of the two studies. In the Exeter patients undergoing surgical operations, preoperative shock was a significant independent prognostic factor only in patients aged ≥70 years, and delayed presentation did not have independent prognostic significance in either of the groups studied. Clearly, a retrospective assessment of shock based on a systolic blood pressure <100 mmHg is questionable, but this parameter was used in the Hong Kong studies. We have no comparative information regarding the adequacy of resuscitative procedures for shock in Exeter and Hong Kong.

Concurrent medical illness was a significant factor at any age but it is unlikely that the medical illnesses were identical in Exeter and in Hong Kong. Unfortunately, the Hong Kong study[9] did not describe these illnesses although the earlier report from the same department[8] listed cardiorespiratory disorders, hepatic precoma, diabetes and renal failure as concurrent medical conditions. All of these were included in the Exeter study together with various types of disseminated malignancy.

In this retrospective assessment, the method of risk stratification also enabled the prediction of mortality in patients undergoing surgery in Exeter, although the system was not so effective as in Hong Kong: the scoring system had an 87 per cent sensitivity and 41 per cent specificity in patients aged $\geqslant 70$ years, and an 82 per cent sensitivity and 74 per cent specificity in patients aged <70 years. Risk scores of 1, 2, or 3 were associated with mortality rates of 27, 55, and 100 per cent in patients aged $\geqslant 70$ years, and the corresponding mortality rates for patients aged <70 years were 17, 38, and 100 per cent.

These results suggest that some form of risk stratification should be used in the selection of surgical procedures for patients presenting with perforated peptic ulcers, particularly in the large numbers of elderly subjects who have an increased mortality risk. It has yet to be established that such a policy will save lives since a reduction in the number of definitive procedures might simply result in a further increase in the mortality rate associated with simple suture. Moreover, as Johnston[10] has pointed out, simple suture of duodenal ulcers is not devoid of complications. Nevertheless, we feel that there is a strong case for greater caution in the use of definitive procedures in elderly subjects since the majority of patients have acute rather than chronic ulcers, and our experience suggests that the risks of definitive operations are higher in the elderly.

The principal concern regarding the use of suture operations for perforated duodenal ulcer is that a proportion of patients treated by this method may have continuing problems with ulceration either immediately or within a few months of surgery, but this concern has been reduced by the finding that the use of the histamine antagonist drugs largely prevents such problems[15].

Recent reports of the treatment of patients with perforated duodenal ulcer in Ireland[16] and in Hong Kong[17] have suggested that 70–75 per cent of cases may be successfully managed by conservative non-operative treatment using nasogastric intubation and histamine antagonist drugs. However, it should be noted that the majority of patients treated in these studies were not elderly, and the safety of a non-operative treatment policy for perforated duodenal ulcer in the elderly has yet to be established.

The smaller number of patients presenting with perforated gastric ulcers have a worse prognosis than those presenting with duodenal ulcers. In this study the majority of such patients were aged $\geqslant 70$ years, and there was a 41 per cent perioperative mortality. Some of these ulcers are giant lesions and nothing short of a definitive operation (usually a gastrectomy) will be adequate treatment. However, most ulcers are small acute lesions, and we believe that the same rules of risk stratification should apply in these patients. Simple suture is adequate treatment for such ulcers provided that biopsy material is obtained for histological examination.

The risks attached to surgical operations for perforated peptic ulcer may be reduced by greater involvement of consultant surgeons in the management of such cases although few deaths in the present study were attributed to iatrogenic or potentially avoidable complications. The high mortality rates encountered in Exeter and elsewhere in the UK[5,6] surely justify such attention and a regular audit of the outcome of perforated peptic ulcer.

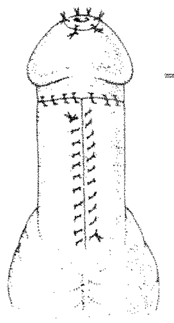
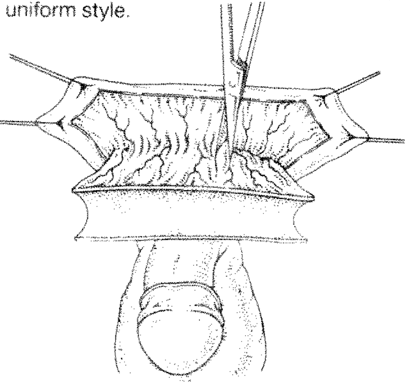
- ★ **Substantially revised and expanded**
- ★ **Many new contributors**
- ★ **Lavish illustrations with most drawn afresh**
- ★ **Indispensable companion to paediatric surgical practice**

Although much of the material has been largely rewritten and revised, the fourth edition of **Paediatric Surgery** retains the style and high standards which characterize the Operative Surgery Series.

The increased size and scope of the book reflect the rapid development of the specialty over the last few years. The first part consists of new chapters on transport, pre- and postoperative management and anaesthesia, and most other sections, particularly that on the head and neck, also contain new material. Within each chapter, the coverage has been broadened to include not only indications for the operation, but also the postoperative complications and statistics on morbidity and mortality. The number of contributors has grown to 65 and the list includes names of leading authorities in the specialty in Britain and around the world. Most of the illustrations have also been redrawn in a uniform style.





This comprehensive collection of techniques provides clear and practical advice for all surgeons who operate on children. It continues to be an indispensable companion to paediatric surgical practice.

Contents: Transport of surgical neonate · Pre- and postoperative management · Paediatric anaesthesia · Head and Neck · Thorax · Abdominal wall · Gastrointestinal tract · Liver and portal system · Neoplasms and endocrine surgery · Urological · Genital · Neurosurgery · Limbs · Trauma · Index.

...With the FEP-Ringed GORE-TEX® Vascular Graft with Removable Rings

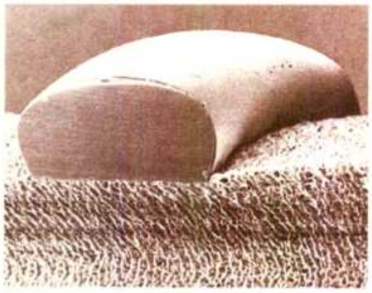
Now you can tailor a GORE-TEX® Vascular Graft to fit your patient and your procedure.

FEP-RINGED GORE-TEX® Vascular Grafts with REMOVABLE RINGS have the same basic construction as other GORE-TEX® Vascular Grafts - but with RINGS THAT CAN BE REMOVED without affecting the integrity of the graft wall. You can remove the rings - quickly, easily and safely - without damaging the graft and without compromising the unique reinforcing film which protects the graft from aneurysmal dilatation.

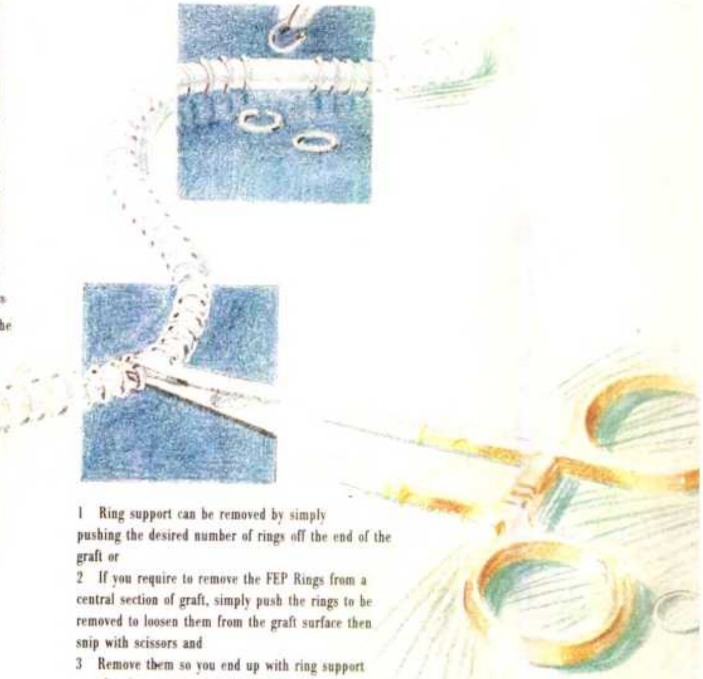
The result is a graft with all the same characteristics as other Vascular Grafts made by W L GORE but with the ring support exactly where you want it.

And the remaining rings have the same adhesion force as those on our existing grafts.

The new graft has been developed without sacrificing any of the qualities that have made GORE-TEX® Vascular Grafts the first choice of vascular surgeons in Britain, and throughout the world.



This demonstrates that the FEP ring is attached to a GORE-TEX® Vascular Graft in no way affects the integrity or compliance of the graft wall.



1 Ring support can be removed by simply pushing the desired number of rings off the end of the graft or

2 If you require to remove the FEP Rings from a central section of graft, simply push the rings to be removed to loosen them from the graft surface then snip with scissors and

3 Remove them so you end up with ring support exactly where you want it and no rings where you don't.

® GORE-TEX is a registered trade mark of W L Gore & Associates (UK) Ltd.

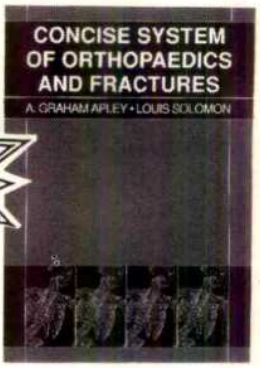
CONCISE SYSTEM OF ORTHOPAEDICS AND FRACTURES

A. Graham Apley MB BS, FRCS, FRCSEd (Hon)
Consulting Orthopaedic Surgeon, St Thomas' Hospital, London, UK
Emeritus Consultant Orthopaedic Surgeon, The Rowley Bristow Orthopaedic Hospital, Pyrford, and St Peter's Hospital, Chertsey, Surrey
Editor, *Journal of Bone and Joint Surgery* (British Issue)

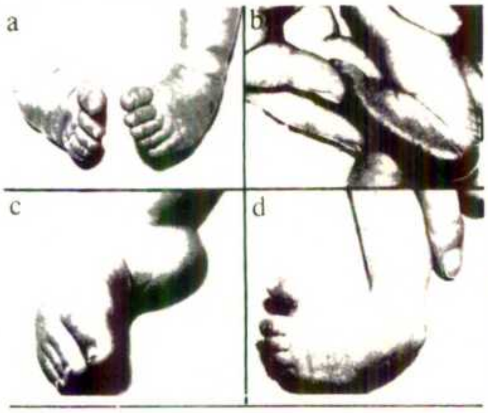
Louis Solomon MB ChB, MD, FRCS, FRCSEd
Professor of Orthopaedic Surgery, University of Bristol, UK
Formerly Professor of Orthopaedic Surgery, University of the Witwatersrand, Johannesburg

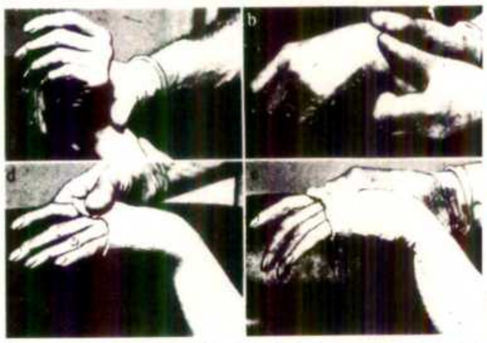
AVAILABLE ON INSPECTION



CONCISE SYSTEM OF ORTHOPAEDICS AND FRACTURES
A. GRAHAM APLEY • LOUIS SOLOMON

★ A shorter, revised version of the classic 'Apley's System' ★ Same systematic presentation – ideal for learning and revising ★ Nearly 500 illustrations, many presented as composites ★ Meets the needs of undergraduate and paramedical students





Apley's System of Orthopaedics and Fractures has for long been an established favourite. But it is a textbook designed primarily for postgraduates, and for many readers it is unnecessarily detailed. This new *Concise System* is a distillation of the larger book and will meet the needs of those looking for an introductory account of modern orthopaedics.

Systematic, balanced and easy to use, the *Concise System* is an outstanding textbook of orthopaedics for anyone seeking a brief account of this large subject. It is also a natural precursor to the more detailed coverage of the subject offered by its larger parent.

Contents

Part 1 General Orthopaedics
Diagnosis in orthopaedics · Infection · Rheumatic disorders · Gout and degenerative arthritis · Bone necrosis · Metabolic and endocrine disorders · Bone dysplasias · Tumours · Neuromuscular disorders · Peripheral nerve lesions · Orthopaedic operations

Part 2 Regional Orthopaedics
The shoulder · The elbow · The wrist · The hand · The neck · The back · The hip · The knee · The ankle and foot

Part 3 Fractures and Joint Injuries
Fracture pathology and diagnosis · Principles of fracture treatment · Complications of fractures · Stress fractures and pathological fractures · Injuries to joints · Injuries of the upper limb · Injuries of the spine, thorax and pelvis · Injuries of the lower limb

Index

October 1988 336 pages 234 x 165 mm Softcover Illustrated – 375 halftones and 95 line drawings 0 407 00325 8 £14.95

Endoscopic haemostasis for non-variceal upper gastrointestinal haemorrhage

R. J. C. Steele

Department of Surgery, University Medical Buildings, Aberdeen Royal Infirmary, Foresterhill, Aberdeen AB9 2ZB, UK

Correspondence to:
Mr R. J. C. Steele

Endoscopic haemostasis can be effective in non-variceal upper gastrointestinal haemorrhage, and should be regarded as potential front-line treatment. Diverse methods are available, and although no single technique has become firmly established, current evidence favours thermal coagulation and injection therapy.

Keywords: Endoscopy, gastrointestinal haemorrhage, haemostasis

Sclerotherapy is well established in the treatment of oesophageal varices[1], but in no sense can it be regarded as curative[2,3]. Endoscopic haemostasis for non-variceal bleeding, however, is more satisfactory as it represents only the first step in the management of a disease which is usually amenable to treatment. Thus, if haemorrhage from a peptic ulcer is controlled by non-operative means, then subsequent elective medical or surgical therapy can usually effect a cure without significant hazard. Furthermore, bleeding from lesions such as Mallory–Weiss tears, arteriovenous malformations and even cancers can be controlled by endoscopic means.

Why, then, is endoscopic haemostasis not more widely practised? Paradoxically, of all the techniques currently available that which was first introduced and which has undoubtedly received the most attention is also the most expensive, complex and difficult to learn. Since the introduction of the therapeutic laser[4], there have been at least 11 controlled trials of endoscopic laser photocoagulation for upper gastrointestinal bleeding[5]. Despite the fact that only six of these have demonstrated any benefit at all, a tacit assumption that laser equipment represents a *sine qua non* may have inhibited many centres from attempting to develop therapeutic endoscopy for non-variceal bleeding. It is, however, becoming increasingly clear that simpler and cheaper techniques are probably as effective as laser therapy, and may indeed have distinct advantages.

The aim of this article is to review and compare the available methods in order to assess the efficacy and applicability of endoscopic haemostasis as it stands today.

The problem

Fibreoptic endoscopy is the method of choice for ascertaining the precise diagnosis in acute upper gastrointestinal haemorrhage[6], and it is known that early investigation is more likely to be helpful than endoscopy which is delayed for 48 h or more[7]. Nevertheless randomized trials have failed to demonstrate any improvement in mortality resulting from routine early endoscopy[6,8], leading to the suggestion that it should be abandoned. Counter to this argument is the finding from Australia that setting up a specialized unit which emphasizes prompt endoscopy has reduced mortality from acute upper gastrointestinal bleeding from 15 to 6 per cent within a few years[9].

These points, although noteworthy, refer only to diagnostic endoscopy, and the emergence of therapeutic manoeuvres has added a further dimension. One of the problems in demonstrating a reduction in mortality for gastrointestinal haemorrhage is the fact that death rates should now be less than 10 per cent, and it would therefore require a trial with very large numbers of patients to demonstrate a significant effect resulting from a specific treatment[10]. Accordingly, another end point is necessary in order to interpret the value of any method, and the most obvious is the need for emergency surgery. Elective surgery for peptic ulcer has been extremely safe for some years now, with many series reporting no mortality[11–13]. Urgent operation for bleeding, however, can be associated with a mortality rate of around 20 per cent[14]. It is therefore reasonable to assume that any significant reduction in emergency surgery would eventually translate into a lowering of mortality rate, to say nothing of perioperative morbidity.

Even a reduction in the number of emergency operations, however, is difficult to demonstrate unless the patients studied are at high risk of continued or further bleeding from the lesion which is to be treated endoscopically. Active haemorrhage would seem to place patients in this category but, as over 70 per cent of all acute upper gastrointestinal bleeding episodes stop spontaneously[15], fortuitous endoscopic visualization of actual bleeding cannot be regarded as an absolute indication for intervention. Moreover, it is now evident that a 'visible' or exposed vessel in an ulcer base is a powerful predictor of rebleeding[16–18] and represents as clear an indication for treatment as does fresh haemorrhage.

It is therefore important that any method of endoscopic haemostasis be subjected to randomized trials in which the control patients are treated conservatively until they fulfil criteria which are not based on endoscopic appearances. Indeed, when adequately documented studies of this type are combined, it would appear that untreated patients with arterial bleeding, non-arterial bleeding and visible vessels come to emergency surgery in only 59, 24 and 38 per cent of cases respectively (*Table 1*). It should also be stressed, however, that the endoscopic appearance of an ulcer is not the only predictive factor. Two recent studies have highlighted the unfavourable prognostic significance of hypovolaemic shock[19,20], and ulcer position is similarly relevant, with rebleeding being more common from lesions situated in the posteroinferior duodenum or high in the lesser curve of the stomach[21].

Endoscopic haemostasis, then, is most appropriate for actively bleeding lesions or visible vessels, and the presence of shock and ulcer position may also help in the selection of patients for treatment. In the following section each technique will be described, and its efficacy will be critically assessed with the emphasis on controlled trials. An attempt will then be made to compare the different approaches using those reports which contain adequate data.

The methods

Different methods of endoscopic haemostasis are legion but the most firmly established are those employing thermal coagulation and injection. The commonly used thermal methods consist of laser photocoagulation, monopolar or bipolar electrocoagulation and the direct application of heat using a 'heater'

SRH, stigmata of recent haemorrhage

probe. Injection therapy has focused mainly on ethanol, the sclerosant polidocanol and adrenaline, the last two being used alone or in combination. Before concentrating on these approaches, however, there are other, less well known techniques which require a brief mention.

Clotting factors in the form of cryoprecipitate or thrombin can be delivered endoscopically to bleeding lesions by spraying[22,23], injection[24,25] or ferromagnetic tamponade[26,27]. Similarly, topical application of microcrystalline collagen can be used to initiate clotting[28,29], and tissue adhesive in the form of trifluoroisopropyl cyanoacrylate has been given a trial[30]. Mechanical methods of endoscopic haemostasis have also been described, utilizing balloon tamponade of the duodenal bulb[31] and direct placement of clips on to exposed vessels[32]. These techniques have met with varying degrees of success, however, and have not been widely investigated or employed.

Laser photocoagulation

Details of the mechanism of laser photocoagulation are available elsewhere[5,33]. Suffice it to say that on contact with tissue, laser light is converted to heat which causes coagulation and vaporization. Two types of laser have been used in the treatment of bleeding ulcers – the argon ion and the neodymium yttrium aluminium garnet (Nd YAG). The former produces a blue-green light which is largely absorbed by haemoglobin so that tissue penetration is low, especially in the presence of blood. The Nd YAG laser on the other hand, has greater tissue penetration[34] and therefore has a theoretical advantage over the argon laser where active bleeding and large vessels are concerned.

In recent years, considerable clinical experience with laser photocoagulation has accumulated, and the most instructive way in which to assess its impact is to examine the 11 controlled trials which have been published. In a study of 136 patients with arterial bleeding, non-bleeding visible vessels or other stigmata of recent haemorrhage (SRH), Vallon and others could not demonstrate an overall significant reduction in the need for emergency surgery or mortality using the argon laser. However, if patients with ulcers inaccessible to laser treatment were excluded from the analysis, a significant improvement was seen in the group with arterial bleeding[35]. In apparent contrast, the study conducted by Swain and his colleagues showed a clear advantage for the argon laser in terms of emergency surgery and mortality in patients with arterial bleeding or visible vessels. However, of 108 patients eligible to enter this trial, 32 were excluded before randomization, largely because the lesion was not accessible to the laser beam[36]. The third argon laser trial was much smaller, but of seven treated patients with arterial bleeding or a visible vessel, none required surgery, compared with five out of nine similar controls[37].

Turning now to the Nd YAG laser, there have been eight trials to date, but four of these were poorly designed or failed to give adequate definitions of the bleeding lesions treated[38–41]. The remaining studies, however, were more carefully constructed and executed, and therefore deserve closer consideration. Rutgeerts and his colleagues randomized 129 patients with non-arterial bleeding, visible vessels or clot, and achieved 100 per cent initial haemostasis in the laser-treated group[42]. They observed no differences in mortality rate or the need for emergency surgery, but laser therapy did produce a significant reduction in clinical rebleeding among the patients with active bleeding. It should be noted that 20 subjects were excluded from this study because of equipment failure and eight because of inability to gain adequate access to the lesion. In a smaller trial from Glasgow, 20 patients with visible vessels were randomized, but of 12 allocated to laser therapy, only eight actually received treatment[43]. Emergency surgery was required in one of the treated patients compared with all eight of the controls, and this constituted a significant advantage for laser photocoagulation even when the untreated patients in the laser group were included.

The largest favourable study of the Nd YAG laser has been that of Swain and his co-workers[44]. This trial recruited 138 patients with arterial bleeding, visible vessels or other stigmata of recent haemorrhage and demonstrated a significant reduction in rebleeding rate, the need for surgery and mortality rate[44,45]. Unfortunately, a large number of eligible patients were excluded from this trial, mainly because of technical difficulty in aiming the laser beam. In the most recently reported trial, Krejs and others randomized 174 patients but did not find any significant benefit from the laser treatment[46]. Before entry into this study 281 potential subjects were excluded, 221 because they were too unstable to be moved to the laser unit, 26 because the laser was not functioning and 34 because the lesion was inaccessible. It is also important to note that only two of the trial patients had active arterial bleeding, and that laser treatment was carried out by, or under the supervision of, five different operators. The poor results of this trial may therefore have been influenced by a tendency to select low-risk patients and to have treatment delivered by multiple operators of variable experience.

In summary, there have been eleven controlled trials of laser therapy for non-variceal upper gastrointestinal haemorrhage, but not all are of similar quality. In six of these reports a significant benefit has been claimed[36,37,41–44], but in fact only four trials have shown a reduction in the need for emergency surgery[36,37,43,44] and only two have demonstrated a significant reduction in mortality rate[36,44]. Furthermore, these benefits must be set against the relatively large number of patients excluded from randomization in at least three of the studies[36,42,44]. There is little doubt, however, that laser photocoagulation can be effective in producing permanent haemostasis, but it is highly operator-dependent, and can only be used for lesions which are favourably situated within the gastrointestinal tract.

Electrocoagulation

Electrocoagulation is an extremely useful haemostatic technique in surgery and can be applied to endoscopic haemostasis. Monopolar electrodes are effective in this respect, but carry the disadvantages of unpredictable depth of thermal injury, adherence to tissue and clot dislodgement[5]. These may be overcome by irrigating the tip of the probe so that it is covered by a film of water (the liquid monopolar electrode)[47] or by employing the bipolar principle. As a conventional bipolar electrode would be difficult to position endoscopically, a multipolar probe (BICAP®, ACMI, Stamford, Connecticut, USA) has been developed, the tip of which carries three equally spaced pairs of bipolar microelectrodes[48].

Despite the problems associated with 'dry' monopolar electrodes they have been reasonably successful in controlling non-variceal bleeding, and four uncontrolled studies have produced impressive rates of initial and permanent haemostasis in actively bleeding lesions using this approach[49-52]. There have been two controlled trials, and in the first Papp reported a significant reduction in rebleeding and need for surgery in patients with non-bleeding visible vessels[52]. In the second trial 37 patients with gastric ulcers exhibiting visible vessels were randomized, and a significant reduction in rebleeding was achieved by therapy, especially among those with active bleeding[53]. Although no complications were reported in these studies, it is important to heed the early experience of Koch and others who produced three perforations with one death after the successful control of bleeding in 15 patients[54]. Clearly, the dry monopolar electrode can be dangerous and must be used with extreme skill and care. There has been less clinical experience with the liquid monopolar electrode, but in one study permanent haemostasis was achieved in 11 out of 15 patients with actively bleeding lesions[55], and in a randomized trial a significant reduction in rebleeding and the number of emergency operations was produced in those patients with non-bleeding visible vessels[56].

The multipolar electrode has received more attention, but although early experience indicated that it could be useful[57,58], two controlled trials have shown no benefit[59,60] and a third, although demonstrating a significant reduction in rebleeding, did not show a reduction in the need for emergency surgery or mortality rate[61]. One investigator, however, has achieved much better results. In a randomized study of 44 patients with actively bleeding lesions, Laine demonstrated significant reductions in emergency surgery, amount of blood transfused, duration of hospital stay and overall cost of treatment[62]. Further, in a separate trial involving 74 patients with non-bleeding visible vessels similar results were reported by the same author[63]. It is important to note that Laine used a 10 Fr probe, as opposed to the small 7 Fr electrode employed by the other workers. This may go part of the way towards explaining the difference in results, although operator skill may have been a crucial factor, as no patient had to be excluded from Laine's series owing to profuse bleeding or poor access.

Direct thermal coagulation

Direct thermal coagulation can be produced by means of a heater probe consisting of an aluminium tip coated by non-stick TEFLON® (Du Pont de Nemour Incorporated, UK) which is heated to 250°C by an inner coil[64]. There is relatively little published clinical experience of the heater probe, but three non-randomized studies testify to its ability to produce initial and, in some cases, permanent haemostasis in bleeding peptic ulcers[65-67]. In two of these reports, particular difficulty was encountered in controlling bleeding from duodenal ulcers[66,67], but this was not the experience of Johnston and others who achieved 100 per cent initial haemostasis in 20 patients, 11 of whom had duodenal ulcers[65].

To date, only one controlled trial of the heater probe has been reported. In this study 43 patients with active bleeding or major SRH were randomized and a significant reduction in rebleeding was demonstrated in the treated group[68]. There was, however, no difference in terms of surgery or mortality rates and there were eight exclusions from the trial for technical reasons[69].

Injection therapy

Injection treatment for non-variceal bleeding has only commanded attention relatively recently. The substances which have been used fall into two categories – sclerosants and vasoconstrictors used alone or in combination. The main sclerosant materials in current use are ethanol and polidocanol, both of which act by thrombosing the bleeding vessel and causing necrosis with subsequent fibrosis of the surrounding tissue[1]. Adrenaline is the only vasoconstrictor which has been formally evaluated, and is presumed to operate via temporary vasoconstriction and platelet aggregation which combine to encourage thrombosis in the bleeding vessel[70].

Using 98 per cent ethanol, Asaki and his colleagues have accumulated the largest series of patients treated by injection therapy. In a multicentre study involving 332 patients with active bleeding or adherent clot, only two continued to bleed, 20 rebled and 10 required emergency surgery[71]. In a much smaller study, Sugawa and others achieved permanent haemostasis in 34 out of 40 patients with actively bleeding lesions using the same method[72]. Polidocanol has also emerged as a clinically useful sclerosant and three uncontrolled studies, one using the substance alone[73] and two employing pre-injection with adrenaline[74,75], have demonstrated its efficacy in both actively bleeding and non-bleeding vessels. To date, there has been one controlled trial of polidocanol in which 113 patients with ulcers exhibiting active bleeding, visible vessels or adherent clot were randomized. The treated group received an initial injection of 1:10000 adrenaline into and around the bleeding point, followed by 1 per cent polidocanol administered in the same way. Overall, there were significant reductions in the need for emergency surgery, amount of blood transfused and duration of hospital stay[76]. Six patients were excluded from this study because their ulcers were inaccessible owing to duodenal deformity.

The use of adrenaline as the sole injectable agent has received scanty attention until recently, but there is now evidence that it may be of value. After an encouraging pilot study[77], a group from Hong Kong has reported on a randomized trial of 1:10000 adrenaline injection which involved 68 patients with actively bleeding ulcers[78]. Strict criteria for selecting patients for emergency surgery were employed, and adrenaline injection was found to produce a significant decrease in the need for such treatment, as well as reductions in the amount of blood transfused and time in hospital. Hirao and co-workers have also reported success with adrenaline, although their technique also involved the injection of hypertonic saline[79]. In this context it is of interest that two groups have produced a marked improvement in the efficacy of Nd YAG laser therapy by prior injection of adrenaline[80,81]. This has been ascribed to good visualization of the bleeding point and elimination of the arterial heat sink[82], but it is equally possible that the vasoconstrictor exerted the major therapeutic effect. The same argument can be applied to combinations of adrenaline and sclerosant.

Comparisons between different methods

There have been relatively few studies comparing different techniques of endoscopic haemostasis. Goff looked at Nd YAG laser therapy and multipolar electrocoagulation in 33 patients with active bleeding or visible vessels[83] and could find no difference. This was a small group, however, and only partly randomized. In a larger, better designed prospective trial, Rutgeerts and others similarly compared the Nd YAG laser with the multipolar electrode and found them to be equally effective[82]. In this study, however, both forms of coagulation were preceded by adrenaline injection, making interpretation of the results difficult.

The Nd YAG laser has also been compared with the heater probe, and in a non-randomized retrospective study Johnston came down in favour of the heater probe. Emergency surgery was required in only 5 per cent of 20 subjects treated by the probe, whereas 17 per cent of the 35 laser-treated patients came to operation[65]. In a three-way randomized trial, however, Northfield and his colleagues have reported significantly less rebleeding with Nd YAG laser treatment when compared with controls, but not with heater probe therapy[84].

Finally, in another three-pronged trial comparing multipolar electrocoagulation, heater probe and non-treated controls, Jensen and others found that both forms of therapy were effective in obtaining initial haemostasis, but that only the heater probe produced a significant reduction in rebleeding and the need for urgent surgery[85].

Although randomized trials may be seen as the ideal way of establishing the best form of endoscopic haemostasis it must be accepted that any investigator will obtain optimum results from the type of therapy with which he or she is most familiar. Until trials that overcome this obstacle are carried out, it will remain necessary to draw conclusions from separate studies. This can be awkward, as stratification of patients into various levels of risk is not always possible from the data in the available literature, but a certain amount of comparative analysis is possible. As outlined in the introduction, only patients with active bleeding at the time of endoscopy or visible vessels are at real risk of requiring emergency surgery or of dying from bleeding. In addition, as can be seen from *Table 1*, those with arterial bleeding are at greater risk than those with simple oozing haemorrhage. It is only instructive, therefore, to compare different studies within appropriate subgroups, and an attempt has been made to do this using three broad categories: laser photocoagulation, electrocoagulation and injection techniques (*Table 2*). Unfortunately, many published reports simply do not contain sufficiently detailed information and cannot therefore be used for comparison. In addition, the groups are clearly heterogeneous and the electrocoagulation results are heavily biased by one study. With these provisos, however, it would seem that while all three methods are roughly equivalent in the treatment of non-arterial bleeding and visible vessels, laser therapy of arterial bleeding is not as effective as electrocoagulation or injection.

Discussion

The current profusion of techniques for endoscopic haemostasis indicates that no one method has gained supremacy. Laser photocoagulation has been in the forefront for a number of years, but careful appraisal of the literature does not inspire great confidence in this approach. Few of the controlled trials have demonstrated clear benefit from laser treatment, and the overall results for arterial bleeding are not impressive. Furthermore, in several trials relatively large numbers of patients had to be excluded because their lesions were inaccessible[36,42,44,46,82], a problem which is less common with other forms of therapy. Equipment malfunction, absence of the laser operator and inability to transfer patients to the laser facility are also frequently cited reasons for treatment failure[36,42-46] and adverse effects including perforation and reactivation of bleeding have been reported[36,46,65,80]. Finally, laser equipment is expensive and its widespread introduction for endoscopic haemostasis cannot yet be justified.

What then, of the alternatives? Electrocoagulation offers a simpler approach, and despite its theoretical disadvantages the monopolar electrode does appear to be useful, although it still requires careful prospective evaluation. Evidence from randomized trials indicates that the 10 Fr multipolar electrode is more likely to be effective than the 7 Fr probe, but it should be stressed that only one investigator has been able to demonstrate a significant reduction in the need for emergency surgery using this device[62,63]. The heater probe is also an attractive concept and shows some promise at an early stage of its clinical development. All these coagulation instruments do carry a risk of extensive tissue damage and perforation, but in practice this does not seem to be a major problem. They also involve extra cost, although not of the same order as laser units.

The final approach is injection therapy which has the attraction of demanding little extra equipment beyond an upper gastrointestinal endoscope. It is not clear, however, which of the injectable agents is most satisfactory. Spectacular results have been obtained from Japan using ethanol[71], but there has been little confirmatory evidence as yet. The sclerosant polidocanol also seems effective, but most of the studies, including the only controlled trial, also utilized preinjection with adrenaline[74-76]. Adrenaline alone would seem to be effective in actively bleeding lesions[77,78] and does not carry the risk of ulcer extension and perforation occasionally seen with sclerosants[71,73]. Having said this, further controlled studies are needed to define the value of adrenaline more precisely, and although no adverse systemic effects have been reported, care must be exercised in its use.

Whatever method is employed it is important to be able to predict which patients will benefit from endoscopic haemostasis and in which it will be unnecessary or fail. Appraisal of the data from randomized trials would indicate that all patients with active bleeding or visible vessels should be seriously considered for therapy at the time of endoscopy, whereas those with minor stigmata of recent haemorrhage or clean ulcers are unlikely to require active treatment. The question of which lesions will not respond permanently to endoscopic intervention is still unresolved, and represents a crucial area for future research. At present the only obvious contraindication is inability to apply the chosen therapeutic modality because of access difficulty or torrential bleeding.

Before concluding this review some technical points should be emphasized. Primarily, it must be understood that even diagnostic endoscopy requires considerable skill in the presence of bleeding, and haemostasis should not be attempted by an inexperienced operator. The endoscopist must also be prepared to carry out gastric lavage, preferably with the aid of an overtube for airway protection[86], and to use vigorous washing in order to obtain a good view[87]. Likewise, the importance of routine repeat endoscopy within 24 h of successful initial haemostasis cannot be overstated, as this affords a valuable opportunity for further therapy should subclinical rebleeding have occurred[78,82].

Endoscopic treatment for non-variceal bleeding is in a state of flux, and the way forward must be to establish the optimum technique or combination of techniques. In a recent leading article, Schuman suggested setting up a multicentre trial to establish whether 'injection therapy can become the frontline endoscopic management for upper gastrointestinal bleeding or whether it is just too good to be true'[88]. Pre-empting this proposal, Rutgeerts has initiated a trial comparing adrenaline alone, adrenaline followed by polidocanol and adrenaline followed by laser therapy[89]. The final result of this study will be of great interest and it may be that other combinations will prove to be of value[90]. In the meantime we may be confident that endoscopic haemostasis will soon become recognized as the initial treatment of choice in most cases of upper gastrointestinal haemorrhage where intervention is indicated. With the present availability of simple and relatively inexpensive methods, it should be feasible to offer this service wherever standard equipment and a reasonable level of expertise exist, and conventional surgery for bleeding may become a rarity in the near future. It therefore behoves all surgical gastroenterologists to work in very close collaboration with their endoscopically trained colleagues or to be endoscopists themselves.

Table 2 *Rates of emergency surgery and overall mortality rate for different forms of endoscopic haemostasis. Omission of figures indicates that the subgroup was not studied or that the data were inadequate*

Dr W. Y. Lau, Surgical 'C' Unit, Queen Elizabeth Hospital, Wylie Road, Hong Kong

In the past 9 years, we have operated on 56 patients with gastrointestinal bleeding of obscure origin. Selective visceral angiography demonstrated the bleeding lesions in 24 of the 30 patients who underwent this investigation. Six of these 24 patients, however, had a negative angiogram initially and the lesions were only demonstrated on a repeat angiogram. The negative initial angiograms were due to: (1) slow bleeding from lesions in two patients; (2) a small bleeding tumour that caused only intermittent jejunojejunal intussusception in one patient; (3) technical fault in one patient; and (4) spasm of the bleeding vascular lesions and their feeding arteries in two patients. We advocate repeat angiography the following day in all patients in whom profuse bleeding continues, and during the next intestinal bleeding in those whose bleeding stops after the initial negative angiography. In patients who have repeated episodes of massive bleeding, and in whom full investigations fail to reveal the bleeding source, repeat angiography carried out 4 weeks after the bleeding has stopped can sometimes demonstrate the vascular lesions.

Keywords: Gastrointestinal bleeding, selective visceral angiography, bleeding lesions

Gastrointestinal bleeding is a common emergency. Fortunately, most of the bleeding lesions are situated at sites easily accessible to endoscopic examination and diagnosis can be speedily made in 80–90 per cent of patients by emergency oesophagogastroduodenoscopy alone[1,2]. In the minority of patients who remain undiagnosed after conventional investigations, many will never bleed again[3,4]. A problem, however, arises when bleeding becomes massive, continuous or recurrent. The investigation of such patients is notoriously difficult, and very often demands a disproportionately large amount of medical time and resources[3].

Selective visceral angiography has proved to be valuable in the diagnosis and localization of these bleeding lesions[4]. The angiogram will be positive in lesions with bleeding rates $>0{\cdot}5$ ml/min (Reference 5) and occasionally in lesions from which the bleeding has stopped[6]. The place of repeat angiography in a patient who has previously had a negative angiography is less well defined. Many clinicians doubt whether repeat angiography will give additional information. Most of them are reluctant to press for repeat angiography and they feel embarrassed when the angiography turns out to be negative again. Thus, information is needed about the value of repeat angiography. In the past 9 years, we have found repeat angiography to be useful and our experience forms the basis of this report.

Patients and methods

From 1979 to 1988, we operated on 56 patients who presented with gastrointestinal bleeding of obscure origin. These patients are defined as patients in whom we failed to find the bleeding source after conventional investigations. The investigations included at least one emergency upper gastrointestinal endoscopy, barium meal, barium enema, sigmoidoscopy and colonoscopy[4]. All patients had massive, continuous or recurrent bleeding. They represented 1·5 per cent of all patients admitted to our unit for gastrointestinal bleeding during the period of study.

A careful history, including a family history of gastrointestinal bleeding and a history of drug intake, was routinely taken. The facial stigmata of Peutz–Jeghers syndrome, blue rubber-bleb naevus syndrome[7] and skin telangiectasia of hereditary haemorrhagic telangiectasia[6] were especially sought in the physical examination. Blood dyscrasias, clotting defects and other metabolic disorders were excluded by laboratory investigations. When conventional investigations failed to reveal the bleeding source, the patients were investigated with ^{99m}Tc-labelled pertechnetate scan, contrast study of the small intestine, selective visceral angiography and ^{99m}Tc-labelled red blood cell scan in the manner we have reported previously[4]. Emergency angiography was carried out whenever the bleeding rate was thought to be $>0{\cdot}5$ ml/min. As far as possible, we tried to localize the lesions before surgical treatment. During the period of investigation, these patients were monitored closely and they were managed actively with blood transfusions.

We repeated the selective visceral angiography the following day in patients in whom profuse bleeding continued, and during the next intestinal bleed in those patients whose bleeding stopped after the initial negative angiography. In patients who had repeated episodes of massive bleeding and in whom full investigations failed to reveal the bleeding source, we carried out repeat angiography 4 weeks after the bleeding had stopped.

Results

Of the 56 patients on whom we operated for occult bleeding lesions, 30 patients underwent selective angiography. Of these 30 patients 24 had the lesions localized by angiography (80 per cent). Six of these 24 patients (25 per cent), however, had a negative angiogram initially. The lesions were subsequently demonstrated on repeat selective angiography (*Table 1*).

The causes of failure of the initial angiography in our patients were as follows (*Table 2*):

1. Slow bleeding from the lesion in two patients.
2. A small bleeding tumour that caused intermittent jejunojejunal intussusception in one patient. The repeat angiography was carried out during the intussusception (*Figure 1a* and *b*).
3. Technical fault in one patient (this occurred in a very obese patient who had a small intestinal arteriovenous malformation). On the first angiogram, the arteriovenous malformation was outside the edge of the radiography and it was missed. On repeat angiography, the lesion was detected in the left lower abdomen.
4. Spasm of the bleeding vascular lesions and their feeding arteries in two patients. The vascular lesions that were detected on repeat angiography were completely absent in the initial angiogram carried out at the time of bleeding. The proximal

AVM, arteriovenous malformation

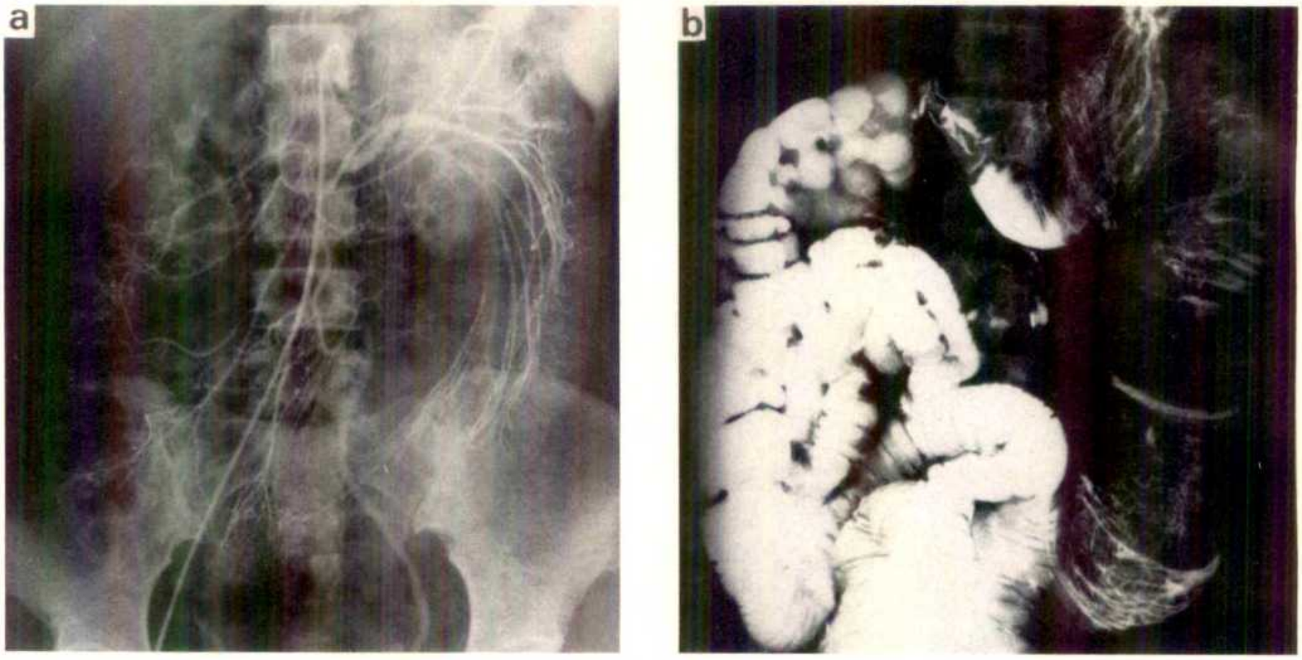

Figure 1 **a** *Late arterial phase of superior mesenteric angiogram, showing a grossly dilated loop of proximal jejunum in the left side of the abdomen.* **b** *Subsequent barium meal and follow-through examination, showing jejunojejunal intussusception in the left side of the abdomen*

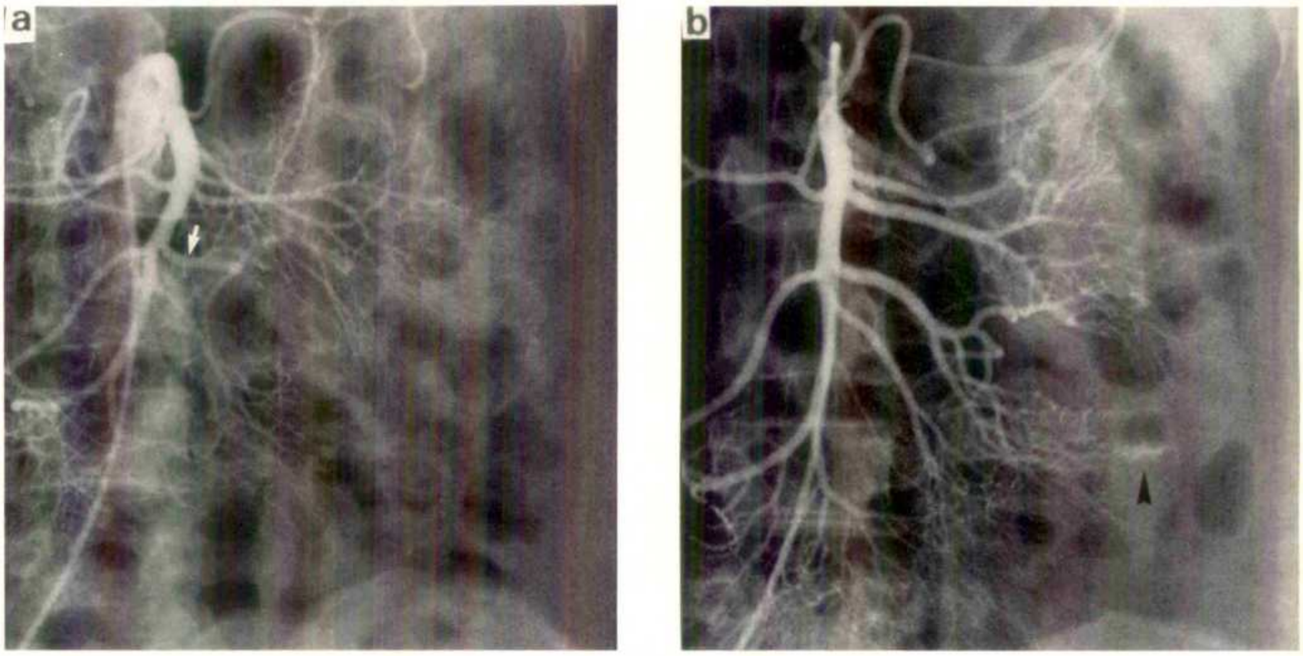

Figure 2 **a** *Initial angiography carried out at the time of bleeding, showing the absence of the small intestinal arteriovenous malformation with attenuation of the proximal portion and complete disappearance of the distal portion of the feeding artery (white arrow).* **b** *Repeat angiography 4 weeks later, showing a small intestinal arteriovenous malformation (arrowhead) and a normal feeding artery*

portion of the feeding artery was attenuated and the distal portion disappeared as a result of spasm in the initial angiogram in one patient (*Figure 2a* and *b*). In another patient, the entire feeding artery disappeared.

Discussion

Selective visceral angiography is important in the management of patients with recurrent gastrointestinal bleeding of obscure origin[4-6,8-10]. Almost all these patients have already had repeated upper and lower gastrointestinal endoscopies, barium meal and barium enema examinations without locating the bleeding lesions[4]. When small-bowel contrast examinations are also negative, approximately 25 per cent of these patients will have intestinal vascular lesions demonstrated on selective angiography. Approximately 20 per cent of the remainder will have other angiographically identifiable lesions, such as leiomyoma, mesenteric artery aneurysm or Meckel's diverticulum[8,11]. Extravasation of contrast into the gut lumen will be demonstrated angiographically for lesions with bleeding rates >0·5 ml/min (Reference 5). The presence of a lesion with a potential to bleed does not mean it is the source of bleeding, unless it is observed directly, endoscopically or radiologically to be actively bleeding[9,10]. This is important because angiodysplasia of the right colon has been found in one-quarter of people over the age of 60 years, without any evidence of bleeding[10,12].

Angiography is also valuable in distinguishing between solitary and multiple lesions[6]. In the latter instance, the location and extent of each lesion are the prime determinants of resectability[6,7]. Furthermore, for patients with a positive angiography, a superselectively prepositioned angiographic catheter will allow intra-operative localization of the segment of gut containing the bleeding lesion[4,13,14].

The importance of repeating the selective angiography has been observed by other workers[15,16] Miller *et al.* commented that, for unknown reasons, intestinal vascular lesions might not be apparent on one examination and yet be obvious on another[15]. Similarly, Marx *et al.* also reported that the reasons for failure of the initial angiography were not always evident. They postulated that the possible causes of failure might be faulty radiological techniques (which was the cause of failure in patient 4) and the small size of the lesions, which might escape careful scrutiny by the radiologist[16] (as in the case of patient 1). Crawford and Russell first used the term 'cryptic' intracranial vascular malformation to denote a small lesion that is not detected by angiography but is identified by pathological examination as a cause of spontaneous intracranial haemorrhage[17]. Patient 1 of our study probably had an intestinal counterpart of this lesion. In patients 1 and 2, extravasation of the contrast medium was not visible in the initial angiograms, probably because the rate of bleeding was slower during the procedure than during the repeat angiograms.

The fact that vascular lesions and the distal portions of their feeding arteries may not be visualized in the initial angiography but are evident on repeat angiography (as in patients 5 and 6) suggests the probability of spasm of these abnormal vascular channels and their feeding arteries. This may be a physiological response to bleeding, so that blood may not pass through the channels during angiography[16]. Transient spasm of intracranial arteriovenous malformations and their feeding vessels after haemorrhage has been reported[18], and there is no reason why this cannot occur in intestinal vascular lesions. Indeed, this haemodynamic change has been postulated to be one of the possible causes of failure of the initial angiography in patients with intestinal arteriovenous malformation[16] and we were able to demonstrate its existence in patients 5 and 6.

In patient 3, we were fortunate to have repeated the angiography during an attack of intussusception. Otherwise, the small smooth muscle tumour forming the head of the intussusceptum would have been too small to be demonstrated by angiography.

From our experience, we advocate that angiography should be repeated on the following day in all patients in whom profuse bleeding continues, and during the next attack of intestinal bleeding in those whose bleeding has stopped after the initial negative angiogram For patients who have repeated episodes of massive bleeding, and in whom full investigations including angiography during an attack of bleeding fail to reveal the bleeding source, repeat angiography carried out 4 weeks after the bleeding has stopped can sometimes demonstrate the vascular lesion.

Rotherham S60 2UD, UK

The admission rates for duodenal ulcer (DU) and the effect of H_2-receptor antagonists (H_2RA), introduced in the Trent Region of the UK in 1977, were examined. The admission rates are expressed per 10^6 of resident population. The use of H_2RA has risen 3·7-fold (from 1978 to 1983), yet overall admission rates for perforation have changed little: 99 in 1972–76 (pre-H_2RA period) compared with 103 in 1977–84 (H_2RA period). Admission rates for haemorrhage have risen by 8 per cent, from 130 to 140 ($P < 0{\cdot}01$). However, the overall rates conceal large increases ($P < 0{\cdot}01$) in the admission rates for those aged ≥65 years, of 33 per cent (from 264 to 352) for perforation and of 28 per cent (from 381 to 489) for haemorrhage. Emergency admissions for uncomplicated DU were unchanged: 88 in 1972–76 and 89 in 1977–84. However, the proportions operated on fell by 58 per cent ($P < 0{\cdot}01$), from 30 per cent of admissions in the pre-H_2RA period compared with only 12 per cent in the H_2RA period. Waiting-list admissions for uncomplicated DU fell by 43 per cent, from 187 to 106 ($P < 0{\cdot}01$), and the proportions operated on fell from 162 to 76; the combined effect resulted in a reduction of 53 per cent in the operation rates ($P < 0{\cdot}01$). In Rotherham, the use of H_2RA has risen 6·2-fold (from 1978 to 1983) and they were generally used intermittently in 1976–78 and later for maintenance therapy and high-dose treatment. Yet admissions for perforation and for haemorrhage were unchanged. Emergency admissions for uncomplicated DU rose by 40 per cent, from 130 in 1972–75 to 182 in 1976–84, but the proportions operated on fell markedly, from 20 to 6 per cent ($P < 0{\cdot}01$); waiting-list admissions fell in 1976–78 by 29 per cent and in 1979–84 by 73 per cent. The proportions operated on in the three periods fell from 74 to 53 per cent and 25 per cent respectively and these two factors led to decreases in elective surgery of 50 per cent in 1976–78 and 91 per cent in 1979–84 ($P < 0{\cdot}01$). Thus, H_2RA have not reduced emergency admissions in DU patients but they are associated with a reduction in waiting-list admissions and in the numbers operated on for uncomplicated DU; where the drugs have been used more intensively, the decrease has been even more marked. Much of this decline can be attributed to the changing natural history of the disease; however, when used intensively, H_2RA have a significant additional effect.

Keywords: Duodenal ulcer, elective surgery, perforation, haemorrhage, effect of age, histamine H_2 receptor antagonists

Hospital admissions for patients with duodenal ulcer (DU), both with and without complications, have been steadily declining in the UK since at least 1957[1–3] and in the USA since 1964[4–14]. The causes for this reduction remain unknown. Since 1977, when the histamine H_2-receptor antagonist (H_2RA) cimetidine became widely available, several centres in the UK, Europe and in the USA have reported further reductions in admission rates which have been attributed to the effectiveness of the drug in medical treatment[15,16]. However, the degree of reduction in admission rates of patients with uncomplicated DU or of patients with complications, and the proportions requiring elective surgery, have varied considerably in different parts of the world. It is not known whether this has any relation to the intensity with which cimetidine and more recently ranitidine have been used[17]

This study investigates the effect that the rising use of H_2RA in the Trent Regional Health Authority (RHA) has had on the admission rates of patients with DU, with or without complications, and on the need for elective surgery In addition a similar analysis was carried out among patients with DU admitted in Rotherham (in the county of South Yorkshire, which is in the Trent RHA) where there is a special interest in ulcer disease and where the H_2RA were used earlier and more extensively, to see if this had any greater influence on the admission and operation rates.

Patients and methods

Information concerning admissions of patients with DU was obtained from the Trent RHA Hospital Activity Analysis files, from which we created a special file concerning DU patients. This dealt with the numbers of patients admitted in each year from 1972 to 1984, subdivided by sex, and for age groups under 35 years, 35–64 years and 65 years or more. The data are presented as admission (age- and sex-specific where subdivided as indicated above) or operation rates per 10^6 of resident population (rounded to the nearest whole number). The current resident population in the Trent RHA is $4{\cdot}6 \times 10^6$

The following categories of DU patients admitted were examined (*Table 1*) (1) perforation, including perforation plus haemorrhage, (2)

Some of the data (up to 1983) were presented on a poster at the meeting of the British Society of Gastroenterology, Brighton, UK in March 1985.

Table 1 *Categories of duodenal ulcer patients studied*

Category	8th edition ICD rubrics	9th edition ICD rubrics
Perforation, including perforation plus haemorrhage	532·00 532·01 532·02 532·03	532·1 532·2 532·5 532·6
Haemorrhage	532·91 532·92 532·93	532·0 532·4
Uncomplicated ulcer	532·90	532·3 532·7 532·9

ICD, International Classification of Disease, published by the World Health Organization. The 8th edition covers the period until the end of 1978 and the 9th edition from 1979 onwards. The 8th edition ICD provided only limited subdivisions of duodenal ulcer. To permit detailed analysis, a fifth digit was added by the Trent Regional Health Authority. However, the 9th edition ICD is more detailed than the 8th edition and divides duodenal ulcer into more subcategories. Each of the latter is therefore represented by four digits only

Table 2 *Operations that were searched in the Office of Population Censuses and Surveys coding to define all patients with uncomplicated duodenal ulcer*

Operation	OPCS code number
Partial gastrectomy	423·9
With gastroduodenostomy	423·2
With gastrojejunostomy	423·3
Vagotomy	
With gastroenterostomy	435
With pyloroplasty	436

haemorrhage, and (3) uncomplicated ulcer, subdivided according to admission (a) as an emergency (presumably for pain and/or vomiting) or (b) from the waiting list or as a 'booked' case

The Hospital Morbidity Record (HMR-1) form, from which the Hospital Activity Analysis files are created, allows up to six diagnoses to be recorded for each patient; these diagnoses are coded in order of importance for that particular admission. As we were interested in the incidence of admissions for perforation and for haemorrhage, all patients with either of these two diagnoses were included, irrespective of the coded position. In contrast, in patients with uncomplicated DU operation rates were of interest. To ensure the selection of patients who were admitted primarily because of their DU and not for another unconnected diagnosis or operation in which the DU was recorded routinely in a low diagnostic position, only those patients with DU listed in the first diagnostic position were counted. The numbers of these DU patients without complications who had any of the antiulcer operations listed in *Table 2* were also recorded. However, only the total number of patients operated on is presented.

By classifying the DU patients into three broad categories and by combining the antiulcer operations into one category, and after comparing the routine Hospital Activity Analysis data collected in Rotherham with samples of the individual case notes, we believe that errors in the routine analysis system are negligible. There have been no major changes in the analysis system over the 13-year period studied except for the change from the eighth to the ninth revision of the International Classification of Disease in 1978.

The Rotherham District Health Authority (DHA) has a resident population of approximately 250000. There is a particular interest in peptic ulcer disease in the Rotherham District General Hospital and consequently a greater use of H_2RA in the district compared with the Trent RHA area as a whole and with the national average. Therefore, the effect of this greater use on DU admission in this area has been separately examined.

An index of the volume of H_2RA used per year in the Trent RHA and in the Rotherham DHA was created, based on sales at constant prices. Though cimetidine was available on prescription from November 1976, accurate data on sales based on geographic locations were not available until 1978, which consequently has been used as the base year. However, *Figures 1–4*, which show the rising use of H_2RA, start from 1977, the first full year of cimetidine sales. Less was sold in this year than subsequently, although accurate regional sales data are not available. The lines on the graphs have been arbitrarily interpolated to reflect this fact. Ranitidine was introduced in October 1981; the volume sold since 1981 was converted to a cimetidine-price-equivalent. Thus the figures for the volumes of both drugs sold could be combined. The index reflects overall sales for the drugs and not specifically use related to DU as such information is not available. The data are up to 1983. Thereafter the method of recording sales changed and the use of H_2RA by region or town could not be accurately calculated. Nevertheless, the sales in 1984 exceeded those in 1983 and it is therefore presumed that the use of these drugs for DU is at least as great as in 1983. The H_2RA usage data were estimated with the assistance of the Market Research and Information Department, Smith Kline and French Laboratories Limited, UK.

Our data are presented in two ways. Firstly, a comparison is made of DU admissions for each category examined, before and since the availability of H_2RA: the average of the admission rate in the two periods is examined. Secondly, data are presented as a change in the yearly rate of admission throughout the two periods. This was done to see whether the rate of change in the H_2RA period was greater than in the pre-H_2RA period, in which case the treatment may reasonably be assumed to have a bearing on this change, or whether there was no difference in the rates when it must be assumed that any change due to drug treatment is no greater than that caused by a varying natural history of the disease.

For the Trent RHA data, we have compared the admissions in the years 1972–76, inclusive, with those in 1977–84. In Rotherham, however, cimetidine became available for experimental use in April 1976. We have therefore compared admissions in the years 1972–75 inclusive *versus* 1976–84. Furthermore, to examine the effect of the use of H_2RA on elective surgery, the latter period has been subdivided from 1976 to 1978 inclusive, when cimetidine was principally used intermittently[18], *versus* 1979 onwards when maintenance treatment with cimetidine[19,20], and to a much lesser extent with ranitidine[21], was commonly used and patients with refractory DU were treated with high-dose cimetidine if necessary[22]

Statistical methods

Differences between the mean admission rates in the pre-H_2RA period and H_2RA period were calculated for statistical comparison using the standard errors of the differences. The changes in yearly admission rates were examined by calculating the slopes of the weighted regression lines

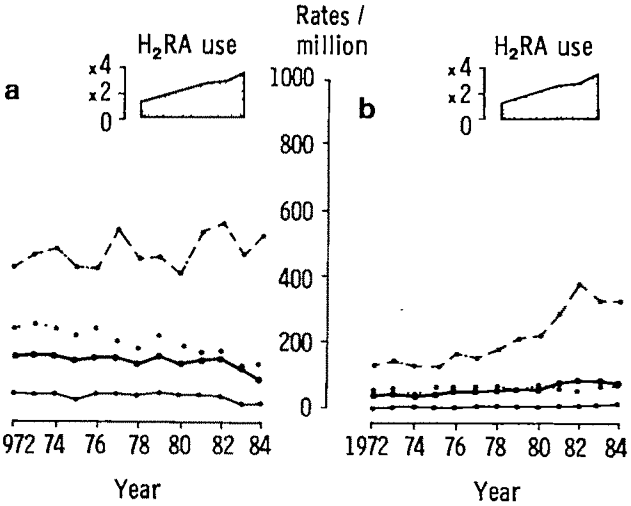

Figure 1 *Admission rates for* **a** *men and* **b** *women with perforated duodenal ulcer, subdivided by age, in the Trent Regional Health Authority, 1972–84. The total volume of H_2-receptor antagonists (H_2RA) used is shown, and is not subdivided by sex. The rise in the total volume of H_2RA used from 1978 to 1983 is shown. The base year is 1978 and the amount used is arbitrarily taken as 100. The increase, compared with 1978, is indicated. Thus, in 1983, 3·7 times more H_2RA was used. – – >65 years, . . 35–64 years, —— <35 years, —— all ages*

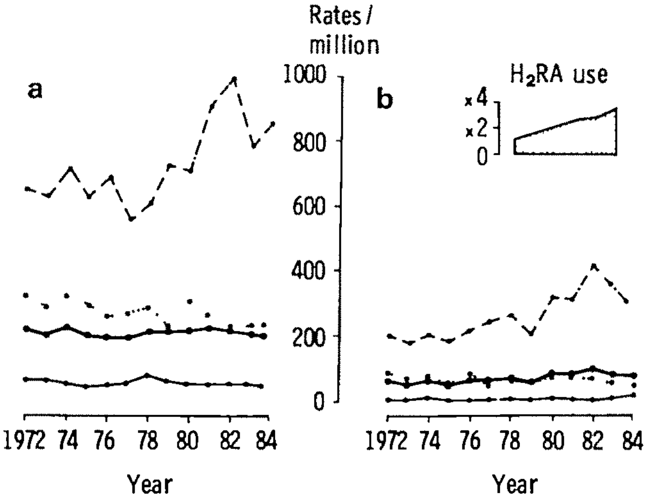

Figure 2 *Admission rates for* **a** *men and* **b** *women with bleeding duodenal ulcer, subdivided by age, in the Trent Regional Health Authority, 1972–84. The total volume of H_2-receptor antagonists (H_2RA) used is shown only in the graph on the right, and is not subdivided by sex. – – >65 years, . 35–64 years, ——<35 years, —— all ages*

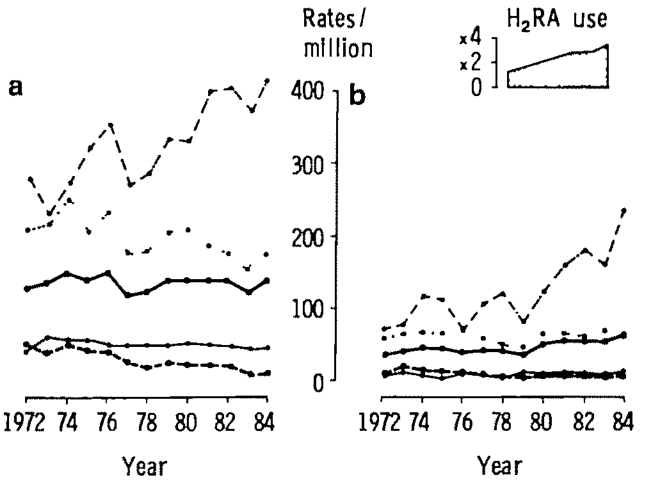

Figure 3 *Rates of emergency admission for* **a** *men and* **b** *women with uncomplicated duodenal ulcer, subdivided by age, and operation rates in the Trent Regional Health Authority, 1972–84 The volume of H_2-receptor antagonists (H_2RA) used is shown only in the graph on the right, and is not subdivided by sex. – – >65 years; . . 35–64 years, ——<35 years, —— all ages, – – – operations*

by the method of least squares[23] The level of significance adopted was three times or more the standard error, i e $P<0 01$

Results

In the Trent RHA the use of H_2RA in 1983 had risen by 3·7-fold compared with 1978, and in the Rotherham DHA the rise was 6·2-fold.

Changes in annual admission rates (per 10^6 of the population) in the Trent RHA: 1972–76 versus *1977–84* (Table 3)

Perforation (Figure 1). The overall annual admission rates for perforation have varied from 90 (in 1975) to 114 (in 1982) with a slight upward trend over the last 12 years on average 99 in the pre-H_2RA period compared with 103 thereafter ($P=0 06$). But these overall figures conceal a 33 per cent rise in the admission rates in people aged ≥65 years, from 264 to 352 ($P<0·01$), the rise being most marked in elderly women.

Haemorrhage (Figure 2). Haemorrhage occurred more frequently than perforation, the annual admission rates varying from 122 (in 1975) to 151 (in 1982) over the past 13 years. The rates have risen by 8 per cent, from 130 in 1972–76 to 140 thereafter ($P<0 01$) But in the elderly (≥65 years) there was a sharp rise of 28 per cent from 381 to 489 ($P<0·01$).

Uncomplicated DU admitted as an emergency (Figure 3) The annual admission rates have varied from 80 (in 1972) to 102 (in 1984) but the average admission rate for the two periods was similar: 88 in 1972–76 *versus* 89 in 1977–84. However, in those aged ≥65 years, the admission rate rose by 36 per cent, from 169 to 230 ($P<0·01$). Though admission rates did not change overall, the availability of cimetidine was associated with a dramatic fall of 58 per cent in the proportion of admitted patients who were operated on, from 30 per cent in the pre-H_2RA period to only 12 per cent thereafter, the operation rates per 10^6 of the population falling from 26 to 11 ($P<0·01$).

Uncomplicated DU admitted from the waiting list (Figure 4). The admission rates were falling even before cimetidine became available, and the reduction was most marked in middle-aged patients (35–64 years). But in the H_2RA era there was a further fall of 43 per cent, from 187 in 1972–76 to 106 in 1976–84 ($P<0·01$). The proportions of admitted patients who were operated on in these two periods also fell: 87 per cent *versus* 72 per cent respectively. The combined effect of the fall in admission and the fall in the proportions operated on resulted in the operation rates decreasing from 162 to 76, i e. by 53 per cent ($P<0·01$).

Uncomplicated DU admitted from the waiting list: changes in rates of admission and of operation (Table 4). The continued fall in admissions and operations in the H_2RA period occurred at a rate not significantly greater than in the years pre-H_2RA

Changes in annual admission rates (per 10^6 of the population) in the Rotherham DHA, 1972–75 versus *1976–84* (Figure 5)

Despite the fact that proportionately about 80 per cent more H_2RA are used in Rotherham than in the Trent RHA per head of population, there was no reduction in emergency admissions. Indeed, admission rates for uncomplicated DU patients admitted as emergencies in Rotherham rose by 40 per cent, from 130 in 1972–75 to 182 thereafter ($P<0·01$). However, the proportions of admitted patients requiring surgery in these two periods fell markedly by 70 per cent, from 20 to 6 per cent ($P<0 01$), the operation rates per 10^6 of the population declining from 27 to 10.

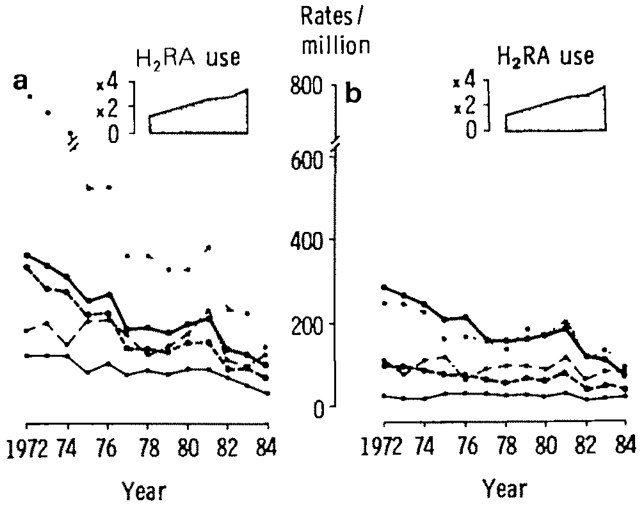

Figure 4 *Rates of admission for* **a** *men and* **b** *women, subdivided by age, from the waiting list, and operation rates in the Trent Regional Health Authority, 1972–84 The total volume of H_2-receptor antagonists (H_2RA) used is shown, and is not subdivided by sex – – >65 years, ... 35–64 years, ——<35 years, —— all ages, – – – operations*

Table 3 *Summary of the main changes in average annual admission and in annual operation rates per 10^6 of resident population in duodenal ulcer patients in the Trent Regional Health Authority*

	Period			
	1972–76 Pre-H_2RA period	1977–84 H_2RA period	Change	
Perforation (admission rates)				
All ages	98·5	102·6		
Age ≥65 years	263·8	351·6	↑33%	($P<0·01$)
Haemorrhage (admission rates)				
All ages	129·6	140·3	↑ 8%	($P<0·01$)
Age ≥65 years	380·7	488·7	↑28%	($P<0·01$)
Emergency admission (uncomplicated DU)				
Admission rates (all ages)	87·6	89·2		
Admission rates (≥65 years)	169·2	230·3	↑36%	($P<0·01$)
Proportions operated on	29·6%	12·3%		
Operation rates	26·0	11·0	↓58%	($P<0·01$)
Waiting list and booked admissions (uncomplicated DU)				
Admission rates (all ages)	187·0	106·2	↓43%	($P<0·01$)
Proportions operated on	87%	72%		
Operation rates	162·4	76·2	↓53%	($P<0·01$)

DU, duodenal ulcer. Data for men and women combined

Table 4 *Changes* in the annual rates of admission and in annual rates of operation in patients admitted from the waiting list, i.e. elective admissions and surgery*

		Admissions	P	Operations	P
Trent Regional Health Authority (excluding Rotherham)					
Pre-H_2RA	(1972–76)	−16·6	<0·01	−15·6	<0·01
H_2RA	(1977–84)	−7·4	<0·01	−6·0	<0·01
Overall	(1972–84)	−10·8	<0·01	−11·1	<0·01
Rotherham District Health Authority					
Pre-H_2RA	(1972–75)	−34·9	n.s.	−32·1	n.s
H_2RA	(1976–84)	−25·1	<0·01	−17·7	<0·01
Overall	(1972–84)	−29·3	<0·01	−26·5	<0·01

* The figures are the slopes of the weighted regression lines and represent changes per 10^6 resident population; n.s , not significant at the 5 per cent level

The most striking change, however, has been in the reduction in admissions from the waiting list and in the proportions requiring elective operation. The admission rates in the three periods 1972–75, 1976–78 and 1979–84 were, respectively, 353, 251 and 97 The proportions of these patients who were then operated on were 74, 53 and 25 per cent respectively, the operation rates per 10^6 of the population for the three periods being 262, 132 and 24. Thus, compared with the pre-H_2RA period (1972–75), in 1976–78 (when H_2RA were used mainly intermittently) and in 1979–84 (when maintenance and high-dose H_2RA therapy was commonly used) admission rates fell by 29 and 73 per cent respectively. This fall, in conjunction with the reduced proportion of patients operated on, led to a fall in elective surgery of 50 and 91 per cent in the two periods respectively.

The reduction in elective admissions and of operation rates in the pre-H_2RA period was not significant, whereas in the H_2RA period the decline was highly significant (*Table 4*).

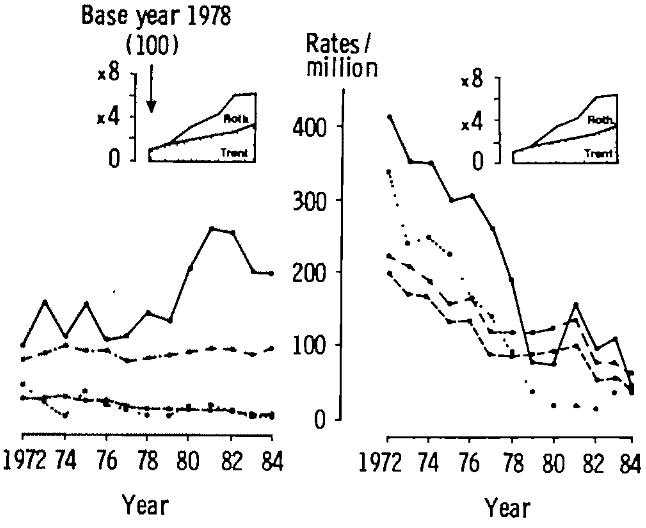

Figure 5 *Comparison of admission and operation rates in patients with uncomplicated duodenal ulcer in the Trent Regional Health Authority (RHA) and in the Rotherham District Health Authority (DHA), 1972–84, and the effect of differing H_2-receptor antagonist (H_2RA) usage The graph on the left shows emergency admissions, and that on the right shows admissions from the waiting list. The admission data here are not divided by sex and age. The volume of H_2RA used in the Trent RHA is the same as in the previous figures, the additional use in the Rotherham DHA is represented by the unstippled portion —— Rotherham admissions, –·– Trent admissions, . . . Rotherham operations, --- Trent operations*

Discussion

Despite the increasing use of H_2RA in the Trent RHA, there has been no reduction in admission rates in patients with DU complicated by perforation or by haemorrhage, nor in patients with uncomplicated DU admitted as emergencies; indeed, admission rates have risen in the elderly, particularly in women Neither has there been a reduction in Rotherham, where the increase in the use of H_2RA has been even more marked. In fact, the true incidence of perforation and haemorrhage is likely to be greater than the admission rate, for several such patients die suddenly at home from their complications and therefore are not included in admission statistics[24]. In contrast, admissions from the waiting list and in the proportions of such patients operated on have fallen; this decrease has been more marked in Rotherham and may be connected with the greater intensity with which the H_2RA are used

It is difficult to be certain why emergency admissions have not declined but at least three factors contribute. Firstly, many patients have no prior ulcer history or have not been investigated for their dyspepsia. Secondly, even in patients known to have DU, there may be few or no heralding symptoms and the first manifestation of an ulcer recurrence is haemorrhage, perforation or violent pain. Thirdly, with the increasing use of non-steroidal anti-inflammatory drugs in the elderly, a higher proportion of patients become vulnerable to developing ulcer disease and its complications[25]. In the first two instances, there is no opportunity to intervene with a healing course of H_2RA. Probably the only way of reducing such admissions is to use maintenance therapy to decrease ulcer relapse rates[26] but this would be applicable only to patients with known duodenal ulcer disease.

The striking fall in elective admissions, and hence in elective surgery, started long before the H_2RA became available and presumably is due (at least in large part) to changes in the natural history of the disease This decline has continued in the H_2RA era. In the absence of controlled studies (which would be impractical), it is difficult to determine how much of this further decline is due to the changing natural history and what proportion can be attributed to elective modern treatment. In the Trent RHA the continued decline during the H_2RA period is at a rate not significantly greater than in the preceding period, suggesting that the increasing use of these powerful drugs did not necessarily have a decisive effect, certainly no greater than that produced by a changing natural history. In the Rotherham DHA, however, the rate of decline in elective admissions and operations in the pre-H_2RA period was not significant, whereas the intensive use of these drugs has been associated with a significant fall (although as the number of patients involved is small, some caution is needed in interpreting these data).

Despite our failure to find a distinct effect of the H_2RA on elective admissions and operations in the Trent RHA, it is hard to believe that such effective therapy does not have any impact: it is common experience that patients who today (and in the past few years) would undoubtedly have been recommended for elective operation can instead be managed medically. Indeed, perhaps it is the alternative to operation offered by H_2RA therapy in many patients that explains, in part, the varied elective surgery rates, reflecting how the choice is exercised (see below).

The explanations that perhaps best fit our observations are that elective admission and surgery have declined dramatically because of a changing natural history; that widespread use of the H_2RA (as in the Trent RHA) has an added effect but one not so large as to be statistically discernible; that intensive use (as in the Rotherham DHA) has a definite additional effect; and that it is the level of intensity of use that determines whether any decline is greater than that produced by a changing natural history

To put our results in perspective, it is pertinent to point out that the lack of overall change in the admission rate for perforation in this study must be compared with the UK admissions, which have been declining over the past 20–30 years[1–3,27]. However, the results from individual centres and from regions are more variable. Several centres have reported an unchanged rate[28–32], one a rising rate[33], and two the opposite[34,35]. Less information is available concerning admissions for haemorrhage except in one centre where admissions fell despite an unchangd rate for perforation[28] Such a variable picture is also seen outside the UK. Various surveys in the USA have reported a reduction in admissions for haemorrhage and perforation[4,5,8], although some centres have not observed any change[9] or have noted an increase in perforation rates (but not haemorrhage)[10] Centres in western Europe have reported admission rates for perforation which are unchanged[36–38,50], decreased[39–41], or even increased[42,43]; in Hong Kong[44,45] there has been a sharp increase. In Athens, admission rates for gastrointestinal bleeding have remained unchanged[46], and in Finland they have increased[38].

Reductions in elective admissions and surgery have also been variable. In the UK, admission rates have steadily fallen since 1968 and the fall has continued since cimetidine became available[1,3]. The reduction in individual centres, however, has been variable and the figures quoted include almost nil[33], 28 per cent[30], 30 per cent[32], 38 per cent[28,29], 39 per cent (with a range of 2–67 per cent)[47] and 70 per cent[34]. A similar pattern has been seen in the USA[4,5,8–14,48] and in western Europe[15,16,36–41,43,49] In contrast, one centre in Australia reported no change[51], and in Hong Kong there has actually been a rise[44,45].

It is difficult to determine why there is such a variation in admission and surgical rates. For perforation and haemorrhage, presumably geographical variation in aggressiveness of ulcer disease, life-style changes, use of anti-inflammatory drugs and other changes in the natural history are the principal determinants. For elective admissions and surgery, however, the way in which H_2RA are used and the criteria to select patients for operation may prove the major determinants. The main indication for elective surgery remains 'failed medical treatment' but how this is defined varies considerably and there are not sufficient studies to relate selection policy directly to the numbers of patients undergoing operation. However, it is common knowledge that in some centres patients are selected if they relapse 2–3 times after healing treatment is stopped. As H_2RA are effective only for the duration they are used, this criterion is unlikely to have much effect in reducing operation rates[52]. In contrast, others prefer to select only patients who relapse on maintenance treatment. Indeed, Venables[53] predicted that such a selection process would reduce operation rates by 58 per cent and in an earlier report observed that in his region it fell by 57 per cent; but others have found that maintenance treatment does not always reduce operation rates as much as expected[54]. In Rotherham we use low-dose maintenance treatment with 400 mg cimetidine nightly (or with 150 mg ranitidine nightly); in those who repeatedly relapse, we use maintenance treatment with 1 g cimetidine (or 0·3 g ranitidine) daily. Elective surgery is now used principally in patients with troublesome refractory duodenal ulcer, i.e. the ulcer remains active (as proved by endoscopy) and causes severe symptoms despite healing treatment with cimetidine at doses of 2 g or 3 g (or with 0·6–0·9 g ranitidine) given for at least 3 months, plus antacids up to 1000 mmol daily; if out-patient treatment fails, we attempt in-patient treatment[22] We suspect that it is the vigorous use of H_2RA which, at least in part, is responsible for the marked reduction in elective surgery in this centre. We have no reason to suspect our patients have milder disease than anywhere else in the UK; indeed, our operation rates in the pre-H_2RA period were considerably higher than for the Trent RHA, despite a lower surgical staffing, which suggests that if anything the disease here may be more aggressive. To put the Rotherham data into perspective, in 1972–75 (pre-H_2RA) on average 60 elective vagotomy and drainage operations were done each year In 1976–78 (when intermittent treatment was used) 42 operations were performed. In 1979–84, when H_2RA were used vigorously, operation rates fell to nine per year.

It has commonly been assumed that the decrease in surgery seen shortly after H_2RA became available was only temporary, that operation was merely being postponed rather than prevented However, over the following years there has been no 'rebound'. Our observations in Rotherham are that some patients who were once well-controlled medically go on to develop refractoriness and ultimately need surgery But such examples are few and are more than offset by the far larger number of people for whom modern medical treatment provides an effective alternative to surgery

There is a feeling that the rising perforation and haemorrhage rates in the elderly represent the consequence of failing to operate electively, and hence curatively, on these patients in their earlier years and instead relying on medical treatment which merely suppresses the disease. Our data do not allow us to draw any conclusions on this point The H_2RA have been widely available only since 1977. Certainly patients who were in their late 50s or early 60s several years ago and were treated medically instead of by definitive surgery could now present with complications and hence add to the rising rate of haemorrhage and perforation in those aged over 65 years. However, this explanation cannot apply to young patients in this study for, even if they developed complications later on, they would still be aged under 65 years, a group in which the complication rate is falling

Recently, the mucosal protectant, colloidal bismuth, has been found to be effective in healing refractory duodenal ulcer[55,56], as has the experimental compound omeprazole, which is perhaps the most powerful antisecretory drug available[57]. These drugs may lead to still further reductions in surgery, although it is extremely unlikely that medical treatment will ever be a complete alternative to elective surgery. It remains to be seen whether the vigorous—perhaps over-vigorous—use of H_2RA in reducing elective surgery is economic or indeed even desirable; for younger patients one approach may be to use the H_2RA to begin with but to go on to early elective surgery in those in whom 'standard treatment' fails[58].

Many doctors are sceptical of the accuracy of the Hospital Activity Analysis, on which our data are based. For logistical reasons, we were unable to check random samples of notes from different hospitals for accuracy in coding other than in Rotherham, where the error rate was low even before the survey began However, an important study on the accuracy of the Hospital Activity Analysis in the Trent RHA comments: 'We feel that the mistrust frequently expressed by consultants in the information produced from Hospital Activity Analysis should be directed towards the quality of the original medical notes than to the Hospital Activity Analysis system itself which, from the results of the study, seems to be quite a good reproduction of what is contained in them.'[59]. Since this survey was done, further efforts have been made in the Trent RHA to improve accuracy; as all coding clerks in the region work to the same specification, variation in error rate is probably small One source of error is confusion between DU and 'peptic ulcer, site unspecified'. However the number so classified is small and misclassification is unlikely to affect our findings. We took the precaution of surveying only easily identifiable diagnoses and of grouping all antiulcer operations. Thus, by using broad headings, errors through misclassification will have been minimized.

In conclusion, we have found that even a marked increase in the use of H_2RA does not diminish emergency admission rates in patients with DU, with or without complications. In contrast, the increase is associated with a decrease in elective admissions and hence in elective surgery. In the Trent RHA, where the use of H_2RA has risen 3·7-fold, the effect of therapy cannot clearly be distinguished from that produced by changes in the natural history of the disease; but in the Rotherham DHA, where the drug use has increased 6·2-fold, there has been an acceleration in the decline, presumably the consequence of the drug treatment.

Japan

In a 7½-year period (from 1 January 1980 to 30 June 1987), 997 patients with gastric cancer underwent gastric resection at the Department of Surgery, Matsuyama Red Cross Hospital, Japan. We studied clinicopathologically 83 patients (182 lesions) with synchronous multiple gastric cancer and compared them with patients who had solitary cancers only in the same period. We found that elderly men had a relatively high incidence of multiple gastric cancer, and that early cancer of the elevated well differentiated type was the most common. Of the 182 lesions, as many as 42 (23·1 per cent) were missed in the preoperative examination. Eighteen of these 42 lesions were found only with the aid of a microscope in sections almost incidentally excised. Small flat lesions tended to be missed. We should always be conscious that other gastric lesions may be present when treating patients with gastric cancer.

Keywords: Multiple gastric cancer

Malignancy is a leading cause of death and gastric cancer is the commonest malignancy in Japan. The incidence of synchronous multiple gastric cancer is variously reported to be 2·07 per cent[1], 5·22 per cent[2], 6·5 per cent[3], or 8·6 per cent[4] and has been increasing recently, probably with advances in the diagnosis of gastric cancer.

Multiple gastric cancer causes several problems in both the diagnosis and the therapy of gastric cancer. Some of these lesions are not suspected before operation and are found almost by chance during histological examinations after surgery performed only to remove the main lesion. How can we reduce the incidence of missed lesions? Are there any clinicopathological characteristics related to the multiplicity of gastric cancers? To seek answers to these questions, we conducted a retrospective study of 83 consecutive patients with multiple gastric cancer encountered at the Matsuyama Red Cross Hospital from 1 January 1980 to 30 June 1987.

Patients and methods

During the 7½ years from 1 January 1980 to 30 June 1987, 1110 patients with histologically diagnosed gastric cancer were treated at the Department of Surgery, Matsuyama Red Cross Hospital Most of these patients were inhabitants of Ehime Prefecture, Japan. Of these, 997 patients underwent gastrectomy (resection rate 89 8 per cent) and their case notes have been reviewed

There were 83 patients (8·3 per cent) with synchronous multiple gastric cancer and the total number of cancerous lesions in these patients was 182 (72 double, nine triple, one quadruple, and one septuple) The diagnostic criteria for synchronous multiple gastric cancer were essentially those of Moertel *et al.*[1]: (1) each lesion must be of pathologically proved malignancy, (2) all lesions must be separated by intervals of microscopically normal gastric wall; (3) the possibility that one of the lesions represents a local extension or metastatic tumour must be ruled out beyond any reasonable doubt

These cases were evaluated with respect to age and sex, macroscopic type, histological type, lymphatic and venous invasion, accompanying benign lesions, stage, missed lesions, operation performed, and outcome They were compared with 914 patients with solitary gastric cancer operated on during the same period The clinical diagnosis of gastric cancer was made by multiple examinations using barium upper gastrointestinal series and endoscopy, usually with dye spraying and biopsy

Resected stomachs were routinely opened intraoperatively and examined macroscopically by surgeons After fixation with 10 per cent formalin, they were again examined macroscopically by a pathologist and were cut into strips (5 mm in width) for microscopic examination. The strips were taken from the area around the macroscopically suspected lesions. Long strips along the long axis of the stomach were usually taken to determine whether oral and aboral stumps of the resected stomach were free from cancer cells

Clinicopathological descriptions of gastric cancer, including macroscopic classification of early cancer, were based on the General Rules for Gastric Cancer Study in Surgery and Pathology in Japan[5] Statistical evaluation employed the χ^2 test and the generalized Wilcoxon test. Survival rates were calculated by the Kaplan–Meier method.

Results

Of the 83 patients with multiple gastric cancer, 42 had only early gastric cancers (with infiltration limited to either the mucosa or the submucosa, irrespective of lymph node metastasis), six had only advanced cancers, and 35 had both early and advanced cancers. The 83 patients had 182 cancerous lesions in total, of which 134 (73·6 per cent) were early gastric cancers. This rate was significantly higher than that in the 914 patients with solitary cancers, 388 (42·5 per cent) of whom had early lesions ($P<0·01$). An examination of the data on the basis of number of patients also indicates that the patients with multiple cancers had less advanced lesions than those with solitary cancers ($P<0·01$).

Age and sex

The average age of the patients with multiple gastric cancer was 64·2 years and 60·3 years in those with a solitary lesion. This difference was statistically significant ($P<0·01$). As shown in *Figure 1*, the incidence of multiple gastric cancer increased with age. In the group with multiple cancer the male:female ratio was 59:24 (2·46:1), which was higher than the ratio of 601:313 (1·92:1) in the group with solitary cancers ($P<0·01$)

Site

In the patients with multiple cancers the proportion of lesions located in the lower, middle, and upper thirds of the stomach was 54·4, 33·5, and 12·1 per cent, respectively. The values for those with solitary cancers were similar, namely 49·3, 36·7, and 13·0 per cent respectively.

Macroscopic classification of the early lesions (Table 1)

When early gastric cancer was classified macroscopically, the most common type was IIc (superficial depressed) in both groups. The elevated type of gastric cancer occurred more frequently in the multiple group ($P<0·01$).

0007–1323/89/030237–04$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Histological examinations

Differentiated adenocarcinoma (or intestinal type according to Lauren[6]) comprised 49·1 per cent of the cancers in the solitary group and 76·9 per cent of the cancers in the multiple group. This difference was statistically significant ($P < 0{\cdot}01$). In the multiple group, 57 patients had only differentiated lesions, 12 patients had undifferentiated lesions, and 14 patients had both differentiated and undifferentiated lesions. In 11 of these 14 cases, the undifferentiated lesions infiltrated deeper than the differentiated ones.

Lymphatic and venous invasion

It is sometimes difficult to verify Moertel's third criterion for multiple gastric cancer, which states that the possibility that one of the lesions represents a local extension or metastatic tumour must be ruled out[1]. To examine the possibility that the accessory lesion(s) resulted from a spread of the main lesion through lymphatic or venous channels, we compared the lymphatic and the venous invasion by cancer cells in the two groups. Invasion into lymphatic channels appeared in 49·9 per cent and 41·0 per cent of the solitary and multiple groups, respectively. Venous invasion was observed in 25·4 per cent of the solitary group and 27·7 per cent of the multiple group These differences were not statistically significant ($P > 0{\cdot}05$ in both cases).

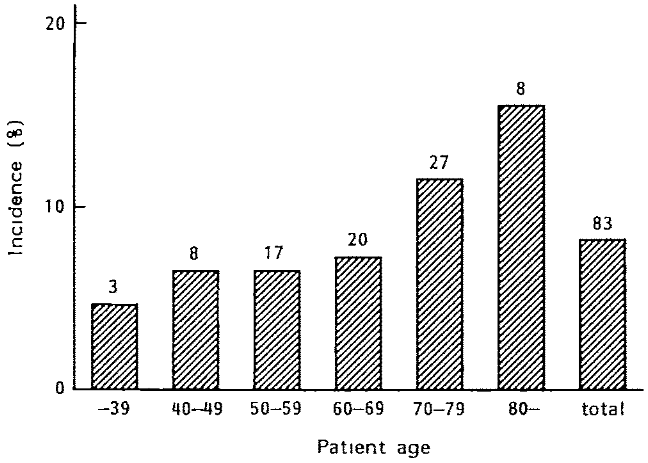

Figure 1 *Relative increase in multiple gastric cancer in each decade. The figure on each column shows the number of patients*

Accompanying benign lesions

There were 15 multiple gastric cancer patients with benign peptic ulcer and 20 of their 31 cancerous lesions were of the depressed type. On the other hand, 13 of 16 lesions from seven patients with adenoma were of the elevated type.

Stage

There was a tendency for the histological stage to be earlier (i.e. stage I or II) in the multiple group than in the solitary group ($P < 0{\cdot}01$) (*Table 2*).

Missed lesions

Forty-two lesions (40 early cancers and two advanced cancers) were missed before operation (*Table 3*). The average diameter of these was 1·01 cm Eighteen of them from 16 cases were not suspected even in the postoperative macroscopic examination but were found histologically in sections taken and examined by chance. These 18 lesions had an average diameter of 0·49 cm and were all intramucosal cancers except for one lesion with submucosal infiltration. The average size of the other 24 missed lesions, which were found in the intraoperative or postoperative macroscopic examination, was 1·41 cm. This was significantly larger ($P < 0{\cdot}01$) than the 0·49-cm average size of lesions found microscopically and was obviously smaller than the 3·94-cm average size of the 115 lesions diagnosed preoperatively

Table 1 *Macroscopic classification of the early lesions in patients with solitary and multiple gastric cancers*

	Elevated			Flat	Depressed			Combined	Not examined
	I	IIa	Other	IIb	IIc	IIc+III	Other

Lesions found microscopically	5	5	8	0	0

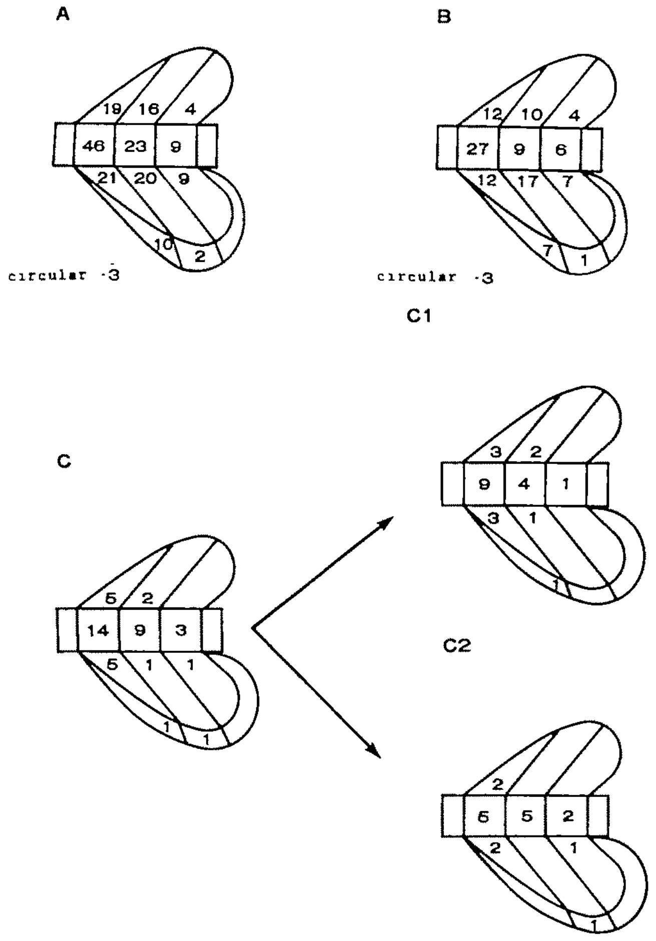

Figure 2 *Distribution of the multiple cancerous lesions in the stomach A distribution of all lesions (n = 182, average diameter $\bar{x} = 2\cdot94$ cm), B distribution of lesions diagnosed preoperatively (n = 115, $\bar{x} = 3\cdot94$ cm), C distribution of lesions missed in preoperative examination (n = 42, $\bar{x} = 1\cdot01$ cm), C1. distribution of group C lesions found macroscopically during or after operation (n = 24, $\bar{x} = 1\cdot41$ cm), C2: distribution of group C lesions found on postoperative histological examination (n = 18, $\bar{x} = 0\cdot49$ cm)*

($P < 0\cdot01$). The distributions of the lesions from these groups are shown in *Figure 2*. There was no apparent difference between the groups in terms of location of the tumours.

Twelve lesions were not detected by upper gastrointestinal radiology but were detected by endoscopy. Ten of these 12 lesions were located on the anterior wall or the lesser curvature of the stomach. Only one lesion was detected solely by barium upper gastrointestinal study.

A macroscopic classification of the missed lesions is shown in *Table 3*. Compared with *Table 1* data, the incidence of flat-type early cancer was high in the group of lesions found microscopically ($P < 0\cdot01$).

When the site of each lesion was assigned to 12 regions of the stomach as shown in *Figure 2*, missed lesions in six cases were located more proximally in the stomach than were lesions diagnosed preoperatively However, in only one case was the operation modified from partial resection to total gastrectomy because of the intraoperative discovery of the new lesions. In another case, the proximal resected margin was not free of cancer cells because the lesion was missed until the postoperative histological examination. However, postoperative examination revealed no residual lesion and the patient is well without sign of recurrence 2½ years after surgery

Operations

It is possible that the larger the proportion of stomach that is removed, the higher the incidence of multiple gastric cancers. However, the frequency of total gastrectomy did not differ significantly between the two groups (28·1 per cent in the solitary group and 32·5 per cent in the multiple group). The 3-year and 5-year survival rates with respect to type of operation, stratified according to histological stages, are shown in *Table 4*.

Outcome

The 5-year survival rate calculated by Kaplan–Meier's method for multiple gastric cancer patients was 72·6 per cent, which is not significantly different from the rate of 66·0 per cent for those with solitary cancer.

Discussion

We have shown that patients with multiple gastric cancer have several clinicopathological characteristics which differ from those of patients with solitary cancer; in particular, elderly men had a relatively high incidence of multiple cancer and early cancer of the elevated, well differentiated type was most common. These characteristics have been noted previously[2,4] although Noguchi *et al.*[3] reported that there was no difference in the macroscopic type while noting preponderance of male and older patients in the group with multiple gastric cancer

Well differentiated cancer of the elevated type is characteristic of gastric cancer in the elderly[7–9]. Intestinal metaplasia becomes predominant with ageing[10,11] and well differentiated carcinoma arises from this metaplasia[6,11,12]. Furthermore, metaplastic mucosa is more prone to oncogenesis than ordinary mucosa[13]. These facts at least partly explain the above relationship between multiple gastric cancer and the elderly The possibility that synchronous multiple gastric cancers fuse together after both vertical and horizontal growth to form a single advanced cancer may explain the high incidence of early cancer in the patients with multiple gastric cancer, as suggested previously[14].

Forty-two lesions out of the 182 (23·1 per cent) in the present study were never suspected in the preoperative examinations. Furthermore, 18 of these 42 lesions were not detected in the postoperative macroscopic examination. Size and macroscopic type of lesion appear important in that the smaller the lesion the greater was the chance of missing it and the flatter the lesion the harder it was to find. We could not detect a trend in the site distribution of the missed lesions, although barium meal studies were less sensitive than endoscopy for lesions located on the anterior wall and lesser curvature of the stomach. At present, we have to admit that it is difficult to diagnose these minute flat carcinomas found only with the aid of the microscope. New methods for the diagnosis of gastric cancer, such as electronic endoscopy with image processing or *in vivo* specific staining of cancerous lesions are awaited with interest. Intraoperative cytology or frozen section diagnosis may also reduce the incidence of missed lesions.

Table 4 *Three-year and 5-year survival rates with respect to type of operation stratified according to histological stage*

Stage	Operation	3-year survival rate (%)	5-year survival rate (%)
I	PG	97·4	97·4
	TG	87·7	87·7
II	PG	87·0	87·0
	TG	74·0	55·5
III	PG	56·0	44·4
	TG	45·3	31·3
IV	PG	13·4	11·2
	TG	9·2	2·3

PG, partial gastrectomy; TG, total gastrectomy

We can reduce the likelihood of missing macroscopic lesions by always bearing in mind the possibility that multiple gastric cancer can occur at any time, especially when diagnosing gastric cancer in aged, male patients with elevated lesions. We should remember that the prevalence of multiple gastric cancer is one out of 12 patients with gastric cancer. The present study also leads us to suspect that undetected minute cancer may exist in the stomach remnants in several patients. However, we have not often encountered gastric cancer arising from the remnant stomach. Furthermore, survival after total gastrectomy does not exceed that after partial gastrectomy when allowance is made for histological stages (*Table 4*) and the quality of life is usually better sustained after partial gastrectomy than after total gastrectomy. Optimistically, there may be spontaneous regression of the cancer in its very early stage, although we do not have data to support this concept. For these reasons, we do not favour a policy of elective total gastrectomy for any patient with gastric cancer. However, it should be emphasized that careful postoperative follow-up is essential to detect any missed lesion(s) in the remnant stomach.

Gastro-oesophageal reflux was measured by 24-h ambulatory oesophageal pH monitoring in 220 patients with symptoms suggestive of gastro-oesophageal reflux disease. By multiple regression analysis it was found that the pressure in the distal oesophageal high pressure zone, the presence of a hiatal hernia, the intra-abdominal length of the high pressure zone, the amplitude of the contraction waves in the distal oesophagus and age all significantly participated in the determination of the amount of gastro-oesophageal reflux. The pressure in the distal oesophageal high pressure zone was the single variable that correlated most strongly to the amount of reflux. Although the amount of reflux increased significantly with increasing weight as measured by Broca's index, this variable did not participate in the determination of reflux by the multiple regression test. The study emphasizes the role of the pressure and intra-abdominal length of the distal oesophageal high pressure zone as the primary antireflux barrier. It also shows that a hiatal hernia plays a role in generating gastro-oesophageal reflux through a mechanism other than affecting the pressure and the intra-abdominal length of the high pressure zone.

Keywords: Gastro-oesophageal reflux, 24-h pH monitoring, distal oesophageal high pressure zone, hiatal hernia, age, Broca's index, smoking, alcohol consumption

The pathophysiological mechanisms in gastro-oesophageal reflux disease have been thoroughly investigated. In the past the presence of a hiatal hernia was considered the main aetiological factor[1]. During the last 20 years, the finding of a hypotensive lower oesophageal high pressure zone has been said to be responsible for reflux disease[2–5]. Other contributing factors often discussed are the length of the high pressure zone (total and intra-abdominal) and the motor function of the oesophagus[6]. To what extent parameters such as age and weight, smoking habits and alcohol consumption affect the amount of reflux has been less frequently reported.

In the present study we have investigated the correlation between these variables and the amount of gastro-oesophageal reflux as measured by 24-h ambulatory pH monitoring in the oesophagus. Furthermore, using a multiple regression test, the relative importance of each variable in determining the amount of reflux has been analysed.

Patients and methods

We have studied 220 patients, 91 women and 129 men, with a median age of 49 years (range 17–75). They were consecutively referred to our oesophageal laboratory because of symptoms suggestive of gastro-oesophageal reflux disease and underwent oesophagogastroduodenoscopy, oesophageal manometry and ambulatory 24-h oesophageal pH monitoring. None had had previous gastric or oesophageal surgery, or had active gastric or duodenal ulcer. Before the investigations, the patients were interviewed about the number of cigarettes they smoked per day and their alcohol consumption. The weight of the patients was expressed as Broca's index· weight in kilograms divided by (height in centimetres minus 100)

Oesophagogastroduodenoscopy was performed with a flexible endoscope after topical anaesthesia of the pharynx. A hiatal hernia was diagnosed if the distance between the diaphragmatic crus and the tubular oesophagus exceeded 2 cm with the patient breathing quietly and with a non-inflated stomach Erosions or ulcerations in the distal oesophagus were found in 67 patients

Oesophageal manometry was performed with a three-lumen water-perfused catheter connected to an Arndorfer (Arndorfer Medical Specialties, Inc, USA) hydrocapillary pump. The catheter had three distal side-holes at 5-cm intervals differing 120 degrees in radial orientation. The stationary pull-through technique was used[7] The catheter was introduced nasally and positioned with all three side-holes in the stomach, it was then pulled back at 1-cm increments. The pressure, total length and intra-abdominal length of the distal oesophageal high pressure zone were calculated as the mean value from the three lumens of the catheter. The pressure was measured end-expiratory at the respiratory inversion point, referring to gastric pressure as zero. The length of the high pressure zone below the respiratory inversion point was considered to be the functional intra-abdominal length. The mean amplitude of the oesophageal contraction waves at dry swallows in the distal 5 cm of the oesophagus was also calculated.

Ambulatory 24-h pH monitoring was performed using portable pH-monitoring equipment (Synectics, Sweden) which consisted of a monocrystal-line antimony pH electrode, a silver–silver chloride reference electrode and a solid state memory box. After calibration at pH 7 and 1 the pH electrode was introduced nasally and placed with the pH recording tip 5 cm above the oral margin of the distal oesophageal high pressure zone previously located by manometry. The reference electrode was placed on the chest and the memory box was worn in a waist-belt The patients were instructed to lead as normal a life as possible and to take normal meals with the exception of acid food and beverages. Medication against gastro-oesophageal reflux such as H_2-blockers and metoclopramide was withdrawn 1 week and antacids 1 day before the investigation. After the monitoring period the data were analysed by a computer program (Esophogram, Gastrosoft, USA) on an IBM personal computer. The amount of gastro-oesophageal reflux was expressed as the percentage of time during the monitoring when pH was <4 in the oesophagus

Statistical methods

Spearman's rank correlation and multiple regression analysis were used[8] $P<0 05$ was considered statistically significant

Results

Correlations between the different variables and the amount of reflux and the results of multiple regression analysis are shown in *Table 1*. Multiple regression analysis allows a multi-dimensional regression between the variables. In other words, it is possible to determine the combination of variables

that together may explain the variation in amount of gastro-oesophageal reflux and to exclude those variables that do not contribute to this explanation. The pressure in the distal oesophageal high pressure zone, the presence of a hiatal hernia, the intra-abdominal length of the high pressure zone, the amplitude of the distal oesophageal contractions and the age of the patient each contributed significantly to this multiple regression. Broca's index, the total length of the high pressure zone, smoking and alcohol consumption did not.

The pressure in the distal oesophageal high pressure zone exhibited the strongest correlation to the amount of reflux (*Figure 1*). The intra-abdominal length of the high pressure zone (*Figure 2*), the presence of a hiatal hernia (*Figure 3*), the contraction amplitude in the distal oesophagus (*Figure 4*), Broca's index (*Figure 5*) and age (*Figure 6*) also correlated significantly to the amount of acid reflux. No significant correlation was found between reflux and the total length of the distal oesophageal high pressure zone, smoking or alcohol consumption.

Discussion

We have shown that the pressure in the distal oesophageal high pressure zone was the single factor that best correlated to the amount of reflux in our patients. Many published studies emphasize the role of the pressure in the high pressure zone as the major antireflux barrier[2–5]. There is evidence that this pressure may not always be related to the competency of the cardia[9]. There is a marked overlap in pressure between normal controls and patients with reflux[10] and the administration of atropine, which reduces the pressure of the high pressure zone, does not increase the indicence of reflux in normal subjects[11]. These findings have led to the suggestion that other factors also are involved in the antireflux mechanism[6]. As shown by multiple regression analysis in the present study, there are other factors that contribute to the determination of the amount of reflux. This means that these factors each influence reflux in a way that cannot be explained by their influence on the pressure of the distal oesophageal high pressure zone. The portion of the high pressure zone below the respiratory inversion point is subjected to changes in the intra-abdominal pressure[12] and an inadequate intra-abdominal portion leads to incompetence[13,14] A short overall length of the high pressure zone has also been cited as causing gastro-oesophageal incompe-

tence[15,16]. This was not seen in our study, probably because an overall length below 2 cm is an unusual phenomenon[16]

Another important component in the antireflux mechanism also seen in our study is the ability of the oesophagus to clear refluxed material[17], reflected by the amplitude of the peristaltic waves in the distal oesophagus[18]. The correlation between oesophageal emptying and acid exposure may, however, also be due to an effect of reflux on oesophageal motor function. The importance of this is supported by studies that have shown that medical and surgical treatment of reflux disease may restore oesophageal peristalsis[17,19]. It has also been suggested that a low pressure in the high pressure zone may be an effect of reflux rather than a cause[20]. Clinical studies have, however, shown that a hypotensive high pressure zone persists after healing of oesophagitis[21].

The presence of a hiatal hernia in our study significantly contributed to the amount of reflux in the multiple regression analysis Since the publication of the classic paper of Cohen and Harris[22] which showed that patients with and without oesophageal symptoms could be separated by the strength of the high pressure zone and not by the presence or absence of a hiatal hernia, attention has been focused away from a hiatal hernia as a pathogenic factor in gastro-oesophageal reflux disease. It has been proposed that a hiatal hernia may prevent reflux by reducing the gastric dilatation[23]. However, a correlation exists between the presence of a hiatal hernia and oesophagitis[24]. This could, at least partly, be due to the impaired clearance of the oesophagus in patients with a hiatal hernia[5],[25]. Furthermore, according to our study, a hiatal hernia influences reflux in some way other than by its influence on the pressure and intra-abdominal length of the distal oesophageal high pressure zone and on oesophageal peristalsis. The reason for this is unknown, but high intrahernial pressures may play a part[24] Other factors that have been previously thought to participate in the antireflux mechanism and that may be influenced by a hiatal hernia are the diaphragmatic pinchcock and the mucosal choke[26].

A weak but significant correlation was found between the age of the patients and the amount of reflux. The influence of age on reflux in normal subjects has been denied[27]. The increase in reflux with increasing age in reflux patients could be due to altered oesophageal motility in the elderly patient[28]

A correlation was also found between reflux and weight expressed as Broca's index. By multiple regression testing, however, Broca's index did not significantly improve the prediction of reflux. Increasing weight thus weakens the antireflux mechanism through the other determinants of gastro-oesophageal reflux.

Smoking did not affect the amount of gastro-oesophageal reflux in our study despite the clinical observations that smoking reduces the pressure in the high pressure zone and promotes reflux[29]. A plausible explanation for this may be that many patients with pathological reflux stop smoking, as smoking worsens their symptoms. Alcohol consumption was not a causative factor in reflux disease in our study but is an important differential diagnosis as alcohol may cause oesophagitis by directly irritating the oesophageal mucosa[30].

The pathophysiological mechanisms in reflux disease have been thoroughly discussed in the literature. The present study shows the relative importance of commonly discussed pathogenetic factors in a clinical population. The coefficient of determination derived from multiple regression analysis is an indication of the extent to which the variability in reflux can be explained by a factor or a combination of factors. *Table 1* shows that the pressure in the distal oesophageal high pressure zone is the single factor that best determines gastro-oesophageal competence and that it explains c. 17 per cent of the variability in acid reflux All the contributing factors in this study together explain 26 per cent of the variability in reflux. In other words, about three-quarters of the variability remains unexplained. There may well be other factors involved in gastro-oesophageal reflux that are not investigated in this study For instance, it

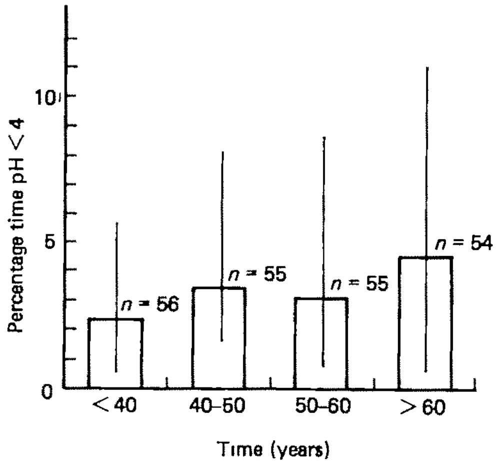

Figure 6 *Relation between age and percentage of time with pH < 4 at pH monitoring. Median and interquartile range. Spearman rank correlation r = 0·12,* P *<0·05*

has been postulated that gastric emptying is deranged in some reflux patients[31]. Acid hypersecretion[32], duodenogastric reflux[31-33] and eating and drinking habits have also been proposed as reflux promoting factors. It must also be remembered that we have only studied the high pressure zone during a short time span at oesophageal manometry while others have shown that the pressure of the high pressure zone may vary with time[34].

It is interesting to note that the three major components contributing to reflux in this study, a low pressure in the high pressure zone, hiatal hernia and a short intra-abdominal length, may be corrected by antireflux surgery At present there is no pharmacological agent available that has an enduring beneficial effect on these factors.

The oesophageal transit time of half a marshmallow was measured radiologically in 17 controls, 28 patients with gastro-oesophageal reflux pre-operatively, 36 patients soon after implantation of the Angelchik prosthesis (2–9 weeks) and in 23 patients later postoperatively (9–48 months). Sixteen postoperative patients also underwent oesophageal manometry. All control and pre-operative patients had a marshmallow transit time of less than 1 min; 67 per cent of the early postoperative patients had prolonged transit and 70 per cent of the late tests were similarly abnormal. Prolonged oesophageal transit as measured by marshmallow swallow correlated well with symptoms of solid food dysphagia. Most, but not all, patients with an abnormal marshmallow swallow had abnormal manometric findings. The oesophageal transit of solid food is significantly slowed after the Angelchik procedure and this is not a transient postoperative phenomenon.

Keywords: Oesophageal transit, Angelchik antireflux procedure

The Angelchik antireflux prosthesis is a horseshoe-shaped silicone elastomer shell filled with silcone gel. It has been extensively used in the treatment of gastro-oesophageal reflux. Clinical results[1] and objective assessment of reflux control[2,3] have been good. Dysphagia is the most common postoperative complication[3,4] and this can be separated into two distinct groups: the first is severe dysphagia, which is uncommon and in our experience is usually due to mechanical problems such as thoracic migration with angulation or the rotation/displacement phenomenon[5]; the second syndrome, which is seen much more frequently, is some difficulty in swallowing solids. Patients often report that certain foods, including bread and meat, 'stick' at the level of their lower sternum. This symptom usually settles spontaneously with time or after vomiting and only very rarely requires intervention—we have twice removed impacted food boluses endoscopically. Most patients learn to chew small amounts of their food well, not to rush their meals and to wash food down with fluid. These symptoms are usually tolerated by patients instead of their reflux pain and previous studies have claimed that this solid food dysphagia is only a transient phenomenon, usually settling within 3 months postoperatively[6].

We have investigated this symptom of solid food dysphagia by liquid barium swallows and have not found any abnormality. This paper describes our experience with the marshmallow barium swallow as a test of solid food oesophageal transit.

Patients and methods

Techniques of marshmallow and barium swallow

A standard liquid barium swallow was performed (100 ml E-Z barium*) and then the patient was asked to swallow half a marshmallow, (approximate diameter 20 mm) without chewing, followed by a further mouthful of barium All investigations were done by a single consultant radiologist (S S.A.). The examination was monitored by intermittent screening on an image intensifier and was recorded on video. The oesophageal transit time of the half marshmallow from the cricopharyngeus to entering the stomach was recorded. The radiographic appearance of the marshmallow is shown in *Figure 1*

Patients studied

A total of 40 patients, 24 of whom were male (median age 52 years), have undergone insertion of the Angelchik prosthesis, all had severe gastro-oesophageal reflux, unrelieved by adequate medical treatment, as documented by endoscopy/manometry and 24 h ambulatory pH monitoring None of the patients had a peptic oesophageal stricture or a primary oesophageal motility disorder pre-operatively.

Controls. Seventeen patients (eight men) with no evidence of oesophageal disease had a marshmallow swallow Their ages ranged from 29 to 70 years (median 48 years).

Pre-operative patients Twenty-eight patients underwent the marshmallow swallow procedure before insertion of the Angelchik prosthesis

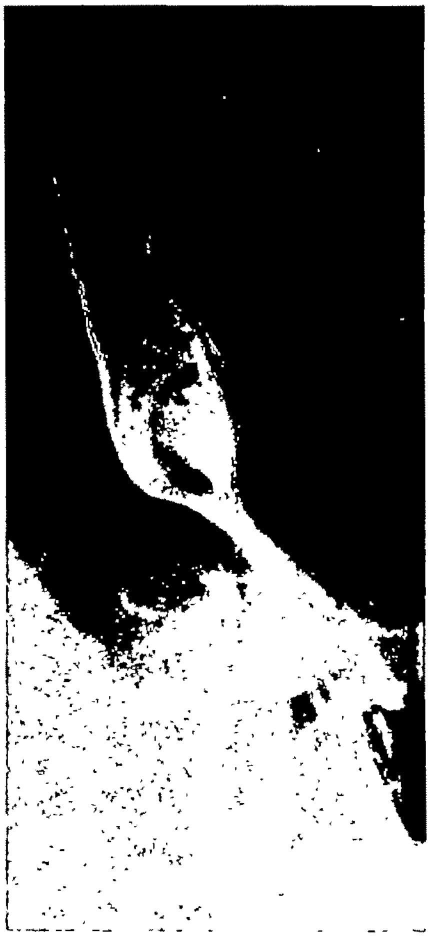

Figure 1 *Marshmallow in lower oesophagus lying just above the Angelchik prosthesis. The radio-opaque marker of the Angelchik prosthesis can be clearly seen*

E-Z barium was obtained from Henleys Medical Supplies, London, UK

0007–1323/89/030245–03$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Post-Angelchik early. Thirty-six patients underwent the marshmallow swallow procedure soon after their operation (2–9 weeks). This included 17 patients who had a pre-operative marshmallow swallow

Post-Angelchik· late Twenty-three patients had a marshmallow swallow procedure performed 'late' at 9–48 (median 33) months after their Angelchik operation.

Manometry

Sixteen patients had oesophageal manometry after insertion of the Angelchik prosthesis Manometry was performed in fasted, supine patients with a triple-lumen polyvinyl catheter perfused at a constant rate (4 ml/h) with distilled water from a low compliance pneumohydraulic pump The catheter was connected to electrically isolated pressure transducers and recordings made onto a multichannel pen recorder. The station pull-through technique was used to identify the position and pressure of the lower oesophageal high-pressure zone. The response of this 'sphincter' to swallowing and oesophageal peristalsis was assessed by wet swallows with 5 ml water.

Results

Marshmallow transit time

Controls Of the 17 controls, all but 4 had an oesophageal transit time of <20 s and the remaining 4 all had transit times ⩽60 s (*Table 1*).

Pre-operative patients. Of the 28 patients investigated before the Angelchik procedure, 24 had a marshmallow transit time of <20 s and the remaining 4 had transit times ⩽60 s (*Table 1*).

Post-Angelchik: early. At the first postoperative marshmallow swallow, 24 of the 36 patients (67 per cent) had a transit time >60 s This included 17 patients who underwent marshmallow swallow both before and after insertion of the Angelchik prosthesis; the transit times are given in *Table 2.* All preoperative times were within the normal range but 10 of the 17 patients had a prolonged marshmallow transit time (> 1 min) postoperatively. The range of transit times was considerable, ten patients having a transit of ⩾3 min.

Post-Angelchik: late. A total of 23 patients underwent a late postoperative marshmallow swallow and in 16 patients (70 per cent) transit was prolonged (> 1 min) (*Table 1*) All of these patients had undergone an early postoperative marshmallow swallow and a comparison of their early/late transit times is shown in *Figure 2.* Of the 16 patients with a prolonged (> 1 min) transit time in the early postoperative period, 3 showed a significant improvement later but only 2 returned into the normal range and 9 patients had slower transit at their later postoperative marshmallow swallow than at their early postoperative investigation. The median marshmallow transit time was 3·5 min in the early postoperative period and 3·8 min in the late postoperative (*P* = n.s.). Of the seven patients with a normal early marshmallow swallow time, two were abnormal at the second investigation.

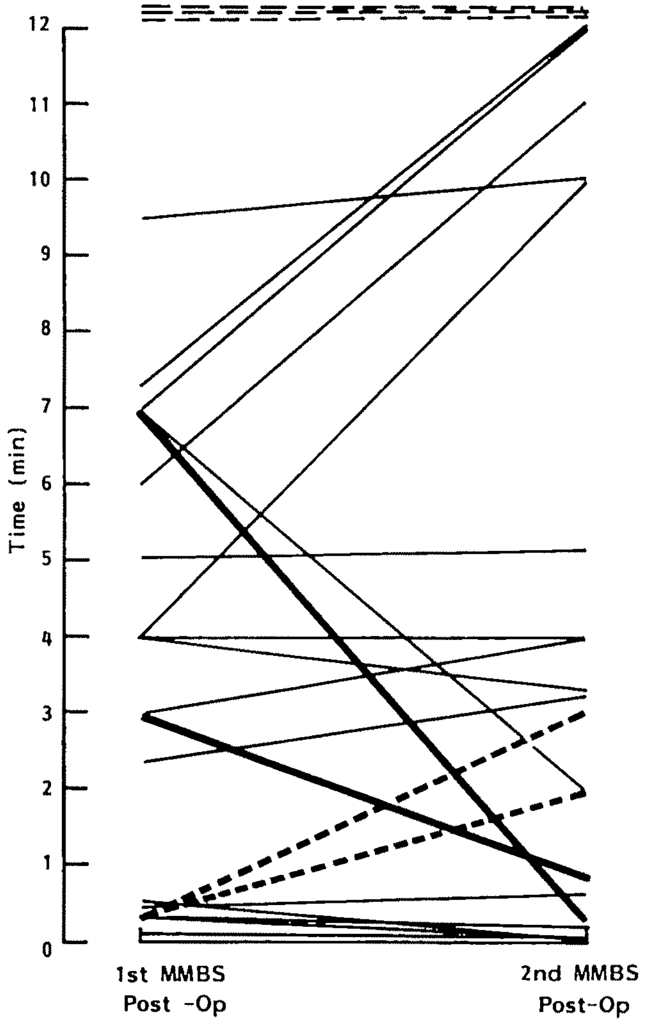

Figure 2 *Marshmallow oesophageal transit times (MMBS) early and late after insertion of the Angelchik antireflux prosthesis:* ——, *2 patients in whom the transit time was prolonged at the first examination but returned to normal with time,* – – –, *2 patients in whom the transit time was initially normal but was prolonged at later examination,* — — —, *3 patients with transit times >12 min;* ——, *the majority of patients (those who had normal transit times continued to do so while those with early abnormalities retained prolonged transit times)*

Correlation of symptoms and marshmallow transit time

Thirty-eight patients complained of some dysphagia for solids after the Angelchik procedure and all of these had a prolonged marshmallow transit time at some time postoperatively In addition, three patients had severe dysphagia due to the rotation/displacement phenomenon[5]; the prosthesis had to be removed in all cases. Only two patients never complained of dysphagia and both had normal marshmallow transit times.

Correlation of manometry and marshmallow transit time

Of the 16 post-Angelchik patients studied by oesophageal manometry, 7 had abnormal oesophageal motility characterized by a non-relaxing lower oesophageal high-pressure zone in 5, an absence of co-ordinated peristalsis in 1 and repetitive peristaltic activity in 1. Of these 16 patients, 10 had a prolonged marshmallow transit time and all 7 patients with a manometric abnormality were identified by marshmallow swallow.

Discussion

The Angelchik prosthesis is widely used in the surgical management of gastro-oesophageal reflux. We have previously reported a high incidence of dysphagia for solid food[3] after its use. This problem has not previously been investigated by the novel technique of marshmallow swallow. There are several advantages to this technique: it is inexpensive and can be performed in any hospital; it allows a liquid examination to be done to exclude structural/displacement problems; the marshmallow floats on top of the barium and allows an assessment of oesophageal peristalsis; and, finally, if the marshmallow becomes impacted in the oesophagus it will slowly dissolve (*c.* 30 min) as it is composed almost entirely of sugar, thus avoiding troublesome bolus obstruction. Although the technique does involve radiation exposure this is limited by the intermittent screening technique. We have shown that oesophageal transit of this bolus is accomplished in $\leqslant 1$ min in controls without any evidence of oesophageal disease and, more importantly, that patients with reflux also have normal oesophageal transit. Previous authors[7,8] report a total of 20 control patients all with a transit time of <1 min using a radionuclide marshmallow technique. We would not argue that all patients with reflux have entirely normal transit—motor abnormalities may well occur secondary to oesophagitis and stricture could clearly interfere with transit—but our group of reflux patients had normal transit pre-operatively. When the same patients were examined after insertion of the Angelchik prosthesis the majority had delayed transit. In all cases the half marshmallow was arrested at the cardia just proximal to the Angelchik prosthesis

We have also demonstrated objectively that this is not a transient postoperative phenomenon in that, of a group of patients who underwent marshmallow swallow a median of 33 months after operation, 70 per cent had prolonged transit. There was a trend to slower transit at the late postoperative marshmallow swallow and more patients had worse rather than improved transit.

The reason for delayed transit of solids following insertion of the Angelchik prosthesis is not clear. The operation certainly gives good control of gastro-oesophageal reflux[3] and none of our patients had a peptic stricture before operation and none developed a peptic stricture postoperatively. Oesophageal manometry postoperatively revealed five patients with a non-relaxing high-pressure zone and all the marshmallows were arrested just proximal to the Angelchik. Symptoms have persisted postoperatively and these factors suggest that dysphagia may be a direct mechanical effect, perhaps due to posterior buttressing of the oesophagus.

Practical advice must be given to patients to encourage them to chew their food thoroughly, to avoid rushing meals and to avoid potentially ulcerogenic tablets, which might well be retained in the lower oesophagus, in favour of liquid formulations.

The Angelchik procedure clearly slows the transit of solid food through the oesophagus and this effect is perhaps permanent. The effects of comparable surgical procedures have not been reported but we are currently evaluating patients randomized to either the Angelchik or Nissen operations.

Four patients underwent liver transplantation in the Cambridge/King's College Hospital programme for malignant primary and secondary apudomas, secreting various peptide hormones and uncontrollable by standard treatment techniques. After transplantation all patients had excellent symptomatic relief and specific peptide hormone levels fell to normal ranges. Two patients remain alive and well after 38 and 22 months, the latter with recurrence of slight tumour-related symptoms and elevation of the specific secretory product. The other two patients died from chronic graft rejection 7 and 8 months after transplantation.

Keywords: Liver transplantation, apudomas, carcinoid syndrome, peptide hormone producing tumours

Current therapy for malignant apudomas including resection, embolization or chemotherapy, as well as pharmacological blocking agents, may give good palliation for a prolonged period both in the primary tumour arising in the liver and hepatic metastatic disease[1–3]. However in cases where such measures are no longer effective and in certain instances where tumour is confined to the liver, transplantation may provide both long-term symptomatic relief and sometimes cure.

In the present report we describe the outcome of four patients transplanted for primary and secondary apudomas, who had distressing and uncontrollable symptoms related to hormone production. The effect of the procedure on the different secretory products is also reported.

Case reports

Case 1

A 35-year-old woman had been aware of a mass in her upper abdomen for more than 10 years before the diagnosis of a massive neuroendocrine type liver tumour was established in 1981 on histological and electron microscopical features Considerably elevated levels of pancreatic polypeptide (>1000 pmol/l, normal <300 pmol/l), gastrin (81 pmol/l, normal <40 pmol/l) as well as urinary vanillinmandelic acid (VMA) (920 μmol/24 h, normal 12–44 μmol/24 h) were detected. In the 4 years following the diagnosis, she experienced increasing lethargy, abdominal discomfort, profuse sweating and weight loss On reinvestigation, in 1985, no extrahepatic tumour spread was found on computed tomography (CT) and bone scans or on staging laparotomy

At transplantation, performed in March 1985, large tumour masses involving both lobes were seen in a 5 7 kg liver, and a tiny tumour deposit, which was found in one hilar lymph node, was removed. Postoperatively peptide hormone levels fell to within the normal range and 38 months post-transplantation she remains well without any signs of recurrence.

Case 2

In 1983, a 47-year-old man was found, on the evidence of an enlarged liver but without any related symptoms, to have an apudoma, he had highly elevated bood levels of somatostatin (>2000 pmol/l, normal <100 pmol/l) and glucagon (84 pmol/l, normal <50 pmol/l) Despite five courses of treatment of Adriamycin® (Farmitalia Carlo Erba, St Albans, UK) and fluorouracil he subsequently developed diarrhoea and hyperglycaemia with intermittent hypoglycaemic attacks, unrelated to insulin treatment in 1984 Additional treatment with mitomycin and antiandrogens also failed to produce a symptomatic response Further investigations with hepatic arteriography revealed an avascular tumour and no extrahepatic tumour spread was found on CT scan

Liver transplantation was performed in August 1985. Histology and electron microscopy confirmed the diagnosis of an apudoma in the resected liver (3 7 kg in weight). The tumour involved both lobes with similar lesions in a small nodule in the body of the pancreas and in enlarged abdominal lymph nodes which had also been resected Post-transplantation the tumour-specific symptoms were relieved immediately and the peptide hormone levels fell to within the normal range. Some 4 weeks postoperatively he developed primary cytomegalovirus infection and 11 weeks later chronic rejection (vanishing bile duct syndrome) was diagnosed on liver histology. His general condition remained good for a further 3 months. Follow-up CT scans showed no tumour recurrence and peptide hormone levels were still within the normal range shortly before his death from chronic rejection in March 1986.

Case 3

A 49-year-old man had an 8-year history of severe diarrhoea and flushing attacks Resection of a carcinoid tumour arising in the small intestine and ligation of two supplying arteries for multiple metastases throughout the liver was performed in 1984. Postoperatively, four courses of cytotoxic therapy with streptozocin and fluorouracil were given as well as continuous treatment with the antiserotonin agents methysergide and cyproheptadine, with only slight symptomatic relief. Although the highly elevated urinary 5-hydroxyindoleacetic acid (5-HIAA) was reduced from 1385 to 390 μmol/24 h (normal range 15–75 μmol/24 h) he started having episodes of severe bronchospasm in 1985 Because of the symptomatic deterioration and impossibility of arterial embolization, liver transplantation was carried out in July 1986.

The resected liver weighed 5 4 kg with both lobes largely occupied by tumour and with tumour involvement of the falciform ligament as well as hilar lymph nodes. All symptoms of the carcinoid syndrome resolved completely after transplantation and the urinary 5-HIAA levels fell to within the normal range After 10 months significantly elevated levels (219 μmol/24 h) were detected again (*Figure 1*) and 17 months after transplantation he began to have occasional diarrhoea. Assessment 20 months post-transplantation found him feeling well without flushing or bronchospasm No tumour recurrence could be detected radiologically or on abdominal ultrasound.

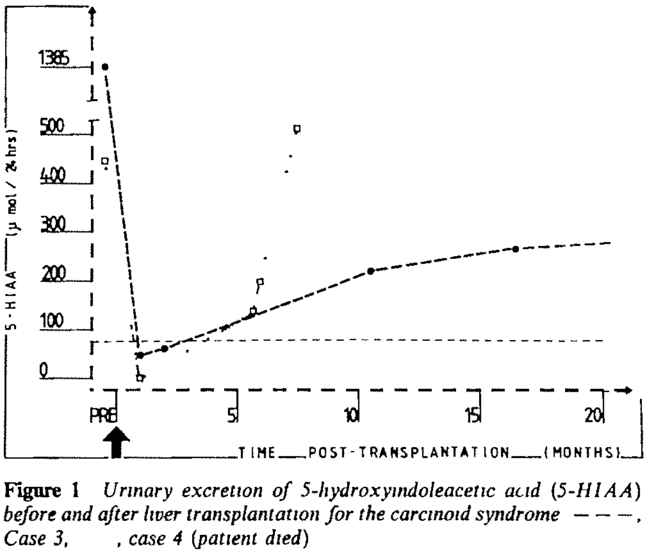

Figure 1 *Urinary excretion of 5-hydroxyindoleacetic acid (5-HIAA) before and after liver transplantation for the carcinoid syndrome — — —, Case 3, , case 4 (patient died)*

0007–1323/89/030248–02$3 00 © 1989 Butterworth & Co (Publishers) Ltd

Case 4

A 53-year-old woman presented in September 1985 with severe diarrhoea, nausea, vomiting and intermittent flushing attacks 40 months after resection of a lung carcinoid tumour. Her liver was found to be grossly enlarged with metastases in both lobes. Hepatic artery embolization was performed on two occasions with good symptomatic relief, high urinary 5-HIAA secretion levels (586 and 407 μmol/24 h, respectively) became undetectable after each treatment for up to 6 months. There was further symptomatic deterioration with distressing diarrhoea, weight loss and massive abdominal distension and an isotope bone scan revealed small tumour deposits in the lumbar spine

Liver transplantation was performed in November 1986. The resected liver weighed 5·6 kg with tumour deposits in both lobes and large hilar lymph nodes. No further abdominal tumour spread was seen She was discharged from hospital after 3 weeks completely free of carcinoid-related symptoms. Subsequently, she had complications relating to the biliary tract anastomosis with cholangitis and after 4 months signs of chronic rejection (vanishing bile duct syndrome) were apparent. The urinary 5-HIAA secretion levels, initially negative, started to rise again 6 months after transplantation (*Figure 1*) but she remained free of carcinoid-related symptoms. Her general condition deteriorated and she died from chronic graft failure complicated by pulmonary infection in July 1987.

Discussion

The indication for transplantation in these four patients was the presence of distressing symptoms in association with excessive peptide hormone secretion, together with massive liver enlargement. In three out of four cases currently accepted methods of treatment[1–3] such as ligation and embolization of the hepatic artery, various combinations of chemotherapy and pharmacological blocking agents could not be repeated or were no longer effective. Both patients with hepatic metastases from carcinoid tumour had had the primary lesions removed previously from the lung and small intestine, respectively. The origin of the mainly pancreatic polypeptide producing tumour in case 1 was likely to have been bile duct epithelium as described previously[4]. The main tumour mass of the somatostatinoma in case 2 was in the liver, but it is possible that the single small tumour node in the body of the pancreas identified and removed during the transplantation was the primary tumour.

All patients had excellent relief of hormone-related symptoms and symptoms related to the massively enlarged liver. Specific peptide hormone levels fell to within the normal range in each patient and two of the patients continue to do well and are alive 38 and 22 months after transplantation. Unfortunately the other two patients developed chronic graft rejection preceded by cytomegalovirus and biliary tract obstruction with cholangitis respectively, and it was these complications and not tumour recurrence which led to their deaths.

Complete symptomatic remission of the carcinoid syndrome was achieved up to 17 months post-transplantation in one patient and to the time of death in the other. Urinary 5-HIAA levels have not been significantly elevated for 6 and 10 months, respectively (*Figure 1*). Liver transplantation for hepatic metastases of different primaries other than apudoma showed poor results in the initial series in the Cambridge/King's College Hospital programme[5]. Only three out of six patients survived more than 3 months and these died between 22 and 41 weeks from recurrent disease. Pichlmayr's group also reported a short period of survival[6]. More encouraging data come from the Vienna group with an estimated 1-year survival of 70 per cent and one patient tumour-free at 3 years; nine patients dealt with had hepatic metastases from radically resected primary colon carcinoma (not exceeding Dukes' C_1) and from a phaeochromocytoma in one case[7]. Of the four patients transplanted for secondary heptic apudomas by Iwatsuki *et al.*[8], three are alive and tumour-free after 2–21 months, while the remaining patient died from perioperative complications.

To date the recurrence rate of primary hepatocellular carcinoma with symptomatic presentation is 64·9 per cent, with 1- and 2-year survival rates of 45 and 38 per cent respectively[5], and it is 77·8 per cent in the Pittsburgh programme[9]. Central and peripheral cholangiocarcinomas have an even worse prognosis with 1-year survival rates of 30·7 and 38·4 per cent respectively. The two patients with primary apudomas thought to be arising in the liver remained free of tumour clinically and radiologically and there was no evidence of elevated peptide hormone levels after 38 months and at the time of death 7 months post-transplantation. Compared with other types of hepatic malignancy, apudomas with their longer history and often lower intrinsic malignancy may represent a relatively favourable group with respect to transplantation.

Cholecystectomy and colorectal cancer

R. J. Moorehead and S. T. D. McKelvey

This review examines the evidence for and against an association between cholecystectomy and colorectal cancer.

Keywords: Cholecystectomy, bile acids, colorectal cancer

There is a considerable amount of epidemiological evidence suggesting that bile acids are aetiologically important in the development of colorectal cancer[1]. While several clinical studies have demonstrated abnormalities in bile acids of those with adenomas and carcinomas of the large bowel[2–4], the precise action of bile acids in tumour promotion or initiation remains to be determined

Certain surgical procedures can affect the size of the bile acid pool with consequent changes in the proportions of bile acids present in duodenal bile Cholecystectomy is one such procedure. It is now generally accepted that the size of the bile acid pool negatively correlates with the level of deoxycholic acid present in bile, i.e. a smaller pool is associated with a greater proportion of deoxycholic acid[5]. While some may argue that it is the presence of gallstones that produces this change in bile acid metabolism[6] it is generally agreed that cholecystectomy patients have a significantly increased proportion of secondary bile acids in bile, chiefly deoxycholic acid[7–10]. As a possible explanation for these changes it is suggested that, while before cholecystectomy the bile acid pool circulates two or three times per meal, after cholecystectomy the pool circulates even during the fasting state. This enhanced circulation results in an increased exposure of bile acids to the degrading action of intestinal bacteria. As a result there is an increased input of secondary bile acids from the intestine into hepatic bile with a corresponding reduction in primary bile acid synthesis owing to increased feedback inhibition[8,9].

Such observations on the effects of cholecystectomy on bile acid metabolism, together with epidemiological, clinical and experimental evidence[11] suggesting possible carcinogenic or co-carcinogenic properties of bile acids have led to increased speculation on the hypothesis that patients with a history of cholecystectomy may have an increased risk of developing colorectal cancer.

While confirmation of such a link would give further weight to the argument which links bile acids with bowel cancer, it would also be of some clinical significance by clearly identifying an at-risk group. There have been several studies investigating the possibility of a link between cholecystectomy and large bowel cancer. The findings of these studies have been varied and in some cases contradictory. In many instances differences in methodology and inadequacy of study group size may account for these variations

The argument for and against an association

There have been many studies suggesting the existence of an association between bowel cancer and cholecystectomy[12–21]. Undoubtedly the best of these is the prospective study by Linos *et al.*[14] who followed up 1681 post-cholecystectomy patients and demonstrated an increased relative risk of developing colorectal cancer of 1·7. They also reported an even more marked risk of 2·1 for the development of right-sided lesions in women (*Table 1*). Unfortunately not all of the other studies go as far as reporting relative risks but those that do claim increased incidences for colonic cancer of between 1·59 and 2·27[15,16] Even higher relative risks of up to 3·5 have been reported for right-sided cancer in women[20], with the highest so far being 4·5 for sigmoid lesions[18], though neither of these studies demonstrated anything more than a trend for an overall increased risk. Caution is required in accepting these increased risks at face value as some of the studies from which they are derived may be flawed through selection of cases and controls In our own study[20] and those from Regula *et al.*[18] and Turnbull *et al.*[16] controls were all drawn from a hospital population It could be argued that such a group is not representative of the general population. Similarly, in the study by Turunen and Kivilaakso[15] both cancer patients and controls were drawn from those undergoing post-mortem examination with the obvious selection bias that this might entail.

Others have divided their cancer patients into cholecystectomy and non-cholecystectomy groups and compared tumour distribution between the two without reference to outside controls[12,13,19]. While this may give information on any potential predisposition for tumour sites in cholecystectomy patients it does not give information on the overall risk compared with the rest of the population. A major criticism levelled against most of these investigations is that they are retrospective case control studies. The finding of an association between two conditions in this type of study could well be due to chance producing a Berksonian bias in the result[14,22]. Therefore one investigation alone suggesting an association between cholecystectomy and colonic cancer might be of interest yet not really significant. That several have observed an association between the two conditions suggests that the result may not be due to chance. Further, the reported increased risk of proximal colonic tumours in some of these studies[12–15,20], suggests that the link between the two conditions may indeed be a causal one. This predilection for right-sided tumours in some studies may be explained by proposing that higher levels of these bacterially modified bile acids are absorbed more proximally in the colon. That some have noticed this finding in women only may be a reflection of the increased incidence of cholecystectomy in women compared with men.

There are more recent reports giving further support to the association. In a colonoscopic study, patients over 60 years of age with more than 10 years having elapsed since their cholecystectomy were found to have an increased incidence of both adenomas and carcinomas of the colon when compared with controls known to have asymptomatic gallstones[17]. A further similar study reported an increased incidence of adenomas in post-cholecystectomy women with a trend for a preponderance of proximal tumours[21].

The evidence against an association between colorectal cancer and previous cholecystectomy[23–33] is open to criticisms similar to those that applied to the studies reporting an

association. Hoare's conclusions cannot be accepted as they came from a small retrospective case control study of only 100 patients[23]. One would not expect significant differences from a study of this size unless the incidence of cholecystectomy in cancer patients compared with controls was very high (*Table 1*). Similarly, although Weiss *et al.*[24] set out to study 243 cancer patients data were only obtained from 141. The authors accept that uncertainty surrounded their results because of the small number of patients studied. From their reported relative risk and confidence intervals one could speculate that had they studied a larger number of patients then evidence to support an association may have been demonstrated.

The investigation by Eriksson and Lindstrom[29], although large (1061 cases), involved cases and controls coming to hospital post mortem Such groups might be considered unrepresentative of the general population. The same criticism could be applied to the smaller studies by Preitner *et al.*[30] and Machnik *et al.*[33]. The case control studies by Vobecky *et al.*[26], Preitner *et al.*[30], Simi *et al* [31] and Spitz *et al.*[32] are similar to the case control studies cited in favour of an association. The same shortcomings of this type of study therefore apply but perhaps more so in view of the comparatively small numbers included in each. In a second part of their study Simi *et al.*[31] made an attempt to follow up 200 post-cholecystectomy patients. Unfortunately endoscopic or X-ray examinations were performed in only a few. Their results are therefore of limited value.

Abrams *et al.*[25] did investigate a large number of both cholecystectomy and cancer cases. However, no matched controls were used thereby casting doubts over the validity of any conclusions. In the population study by Blanco *et al.*[28] the precise number of patients who replied to the questionnaires is not stated. It is therefore difficult to make any comment on their findings.

Of all the papers finding no evidence of an association between colorectal cancer and cholecystectomy, there is only one that stands out[27] In an impressive follow-up of 16773 cholecystectomy cases by Adami *et al.*, no increased risk of large bowel cancer was observed. Clearly, findings such as this cannot be simply dismissed.

Discussion

The precise relationship between cholecystectomy and the development of large bowel cancer remains controversial. The conflicting results from the studies already outlined have done little to settle this important issue. Perhaps much of the conflict is artificial as many of the studies have serious limitations in design, size and make-up of subject groups and controls. Of those studies not demonstrating an association between cholecystectomy and bowel cancer, only that from Adami *et al* [27] stands up to criticism. However, a geographical factor may have to be considered with their results. The incidence of colon and rectal cancer in Sweden has been reported as 16 and 12·8 per 100000 respectively[34]. In Northern Ireland, where an association between cholecystectomy and large bowel cancer has been demonstrated, the incidence of colon and rectal cancer is considerably higher at 21·9 and 18·7 per 100000 respectively. This regional variation in the incidence of colorectal cancer may be an important factor to be taken into account when comparing the different results from Sweden and Northern Ireland This does not necessarily reduce the case against an association as much of the evidence for an association is derived from unsatisfactory studies However, as was the case with the study of Adami *et al.*[27], the findings of the prospective study by Linos *et al.*[14] cannot be simply dismissed. Indeed, the reported increased incidence of right-sided colonic cancer in post-cholecystectomy women from some of the retrospective studies adds weight to their conclusions

In most of the papers mentioned, the selection of suitable controls has been a major problem. Theoretically post-cholecystectomy cases should be compared with age- and sex-matched controls known to have asymptomatic cholelithiasis. The task of obtaining such a group from the general population would be virtually impossible Most authors have therefore had to compromise and use the best available group of controls. It is possible that most of these controls did not have biliary tract disease. As a result the comparison that has been made in many of the papers does not address the effect of cholecystectomy as such but the effect of symptomatic gallstones requiring cholecystectomy *versus* disease-free controls.

The only paper that has managed to make a direct comparison between cholecystectomy cases and those with asymptomatic gallstones is that by Mannes *et al.*[17]. Although they found an increased risk of adenomas and carcinomas in cholecystectomy cases, their study was biased in that all cases and controls were undergoing investigative colonoscopy

If one thing is clear it is that further retrospective studies will not clarify this important issue. The question will only be finally resolved by prospective studies following up post-cholecystectomy patients, with colonoscopy or barium enema, to determine whether the incidence of tumours is really increased We have begun such a study based on the observations of Mannes *et al.*[17]. In an attempt to maximize the yield from screening cholecystectomy patients we are following up those over 60 years of age with 10 years or more having elapsed since surgery with double contrast barium enemas and sigmoidoscopy The selection of controls for this study has proved to be a major problem as it was impracticable to submit a control group to the same investigations. A compromise had to be made and post-mortem patients were used. In an attempt to try to reduce any hospital bias an equal number of cases undergoing non-hospital post mortems were used. Obviously this is an area for potential criticism but nevertheless our preliminary results have shown a fourfold increase in the incidence of adenomas and carcinomas following cholecystectomy[35].

Some groups have reported an increased incidence of large bowel cancer in those with a history of cholelithiasis rather than cholecystectomy[36,37]. However, even if an association between colorectal cancer and biliary tract disease were supported by all, it is possible that there is no direct link between either cholecystectomy or cholelithiasis and large bowel cancer. It may be that the appearance of an association in some reports is because those whose diet predisposed to one disease may well have increased their risk of developing the other. Whether this possible relationship is directly causal or not, those with a history of previous cholecystectomy are readily identifiable. Epidemiologists might suggest that such a group could be worth screening for both colorectal adenomas and carcinomas. However, even if the evidence supporting an association with colorectal cancer were universally supported in absolute terms, cholecystectomy patients may not constitute such a high-risk group to necessitate screening. The reported overall risks of between 1·59 and 2·27 would support this contention.

If such a screening programme were carried out it would have two obvious benefits: first, it would give valuable information on the pathogenesis of large bowel cancer and, secondly, it would determine conclusively whether there is a relationship between cholecystectomy and the subsequent development of colorectal tumours.

Dr R. Andersson

Between 1980 and 1987, nine patients with non-parasitic cysts of the liver were treated with computed tomography-guided percutaneous puncture and evacuation of the cyst contents followed by injection of absolute alcohol as a sclerosing agent. During the same period only one patient was treated with surgery. The patients included seven women and two men with a mean age of 62 years. Three patients had a single cyst and six patients had multiple cysts. The size of the largest cysts varied between 5 and 20 cm (mean 10 cm). Patients with multiple liver cysts had repeated punctures and sclerosing procedures (up to eight times); 50–3100 ml of cyst fluid (mean 650 ml) was drained per procedure. One patient had symptoms of moderate alcohol intoxication; otherwise no complications were noted. Follow-up was performed with computed tomography or ultrasonography for 8–54 months (median 18 months). The results have been considered successful in eight out of nine patients who had cyst regression and reduced symptons. Two patients, however, required additional surgical treatment due to residual and multiple cysts. Computed tomography-guided alcohol sclerotherapy of non-parasitic liver cysts appears to be a safe and effective initial therapy.

Keywords: Liver cysts, non-parasitic, computed tomography, percutaneous aspiration, alcohol sclerotherapy

Non-parasitic liver cysts are either congenital or acquired Congenital cysts are more common and considered to be embryological malformations[1,2]. They can occur as single or multiple cysts with a varying size. There is a female preponderance and symptoms, if they occur, usually first appear in adulthood[3]. The symptoms have mainly been attributed to hepatomegaly, increased pressure within the cyst or pressure on the surrounding organs. Signs of impaired liver function such as jaundice are less frequent[1,4,5]. Most congenital cysts, however, are asymptomatic and require no treatment[1,6]. In a large series of 88 000 laparotomies, 82 solitary liver cysts were found[1] and of these only approximately one-sixth were considered to have caused symptoms

Conservative treatment with aspiration of cyst fluid alone has been associated with a high recurrence rate[6]. Surgical treatment has thus been advocated for all forms of symptomatic liver cysts[1,6].

We wanted to test whether cyst recurrence could be avoided after percutaneous aspiration followed by the instillation of a sclerosing agent In this study we describe a series of patients with non-parasitic liver cysts treated initially with computed tomography-guided percutaneous puncture, decompression and sclerotherapy with absolute alcohol.

Patients and methods

Between 1980 and 1987, nine patients with non-parasitic cysts of the liver were treated with puncture, drainage and injection of absolute alcohol During this period only one patient, with a single cyst not considered accessible for percutaneous puncture, was successfully managed with a surgical fenestration procedure. The patients treated with alcohol sclerotherapy consisted of seven women and two men with a mean age of 62 years (range 40–77 years) Three patients had a single cyst and six had multiple cysts. In seven patients, cysts were limited to the right lobe, while two patients with multiple cysts also had left lobe involvement In three cases a concomitant polycystic renal disease was diagnosed One patient had a post-traumatic liver cyst, while the other patients were considered to have congenital liver cysts The aetiology and localization of the liver cysts are summarized in *Table 1* All patients had symptoms· abdominal pain in eight, a palpable mass in seven and weight loss in one Diagnosis was reached by ultrasonography in seven patients, computed tomography in one and peroperatively (during a renal operation) in one patient. The size of the largest cysts varied between 5 and 20 cm (mean 10 cm) in diameter.

Before the start of therapy the presence of parasitic disease or malignancy was excluded. Under guidance of computed tomography the main liver cyst was punctured with a 5Fr polyethylene catheter sheathed needle The sheath was supplied with several sideholes at the tip to facilitate aspiration of fluid With the aid of a guide-wire the catheter was coiled within the cyst, reducing the risk of displacement when the cyst was evacuated and collapsed. After cyst fluid aspiration, 20–100 ml absolute alcohol (95 per cent) was instilled and as much as possible was reaspirated from the cyst after 10–20 min Liver function tests were performed before as well as 1, 4 and 24 h after alcohol injection Serum ethanol levels were also analysed after the administration of alcohol

Results

Some patients noted slight abdominal pain following ethanol instillation, but otherwise the procedure was well tolerated. One elderly woman had symptoms of moderate alcohol intoxication; her serum ethanol was 8·7 mmol/l, 4 h after alcohol injection. No other complications were noted. Patients with multiple liver cysts had repeated punctures and alcohol instillations at intervals up to eight times before the cyst disappeared. A total of 29 punctures and injections were performed (3·2 procedures per patient) A mean of 650 ml fluid was drained per puncture with a range of 50–3100 ml. The amounts drained gradually diminished with a mean of 1230 ml drained at the first puncture, 540 ml at the second, and 320 ml at the third. Liver function tests were unaffected by the treatment. The patients were followed with computed tomography or ultrasonography for a median of 18 months (range 8–54 months) after treatment. The results were considered good or excellent (*Figure 1*) in eight of the nine

patients, all demonstrating regression of the cyst on computed tomography. Clinically six patients became symptom-free, two had reduced symptoms and one patient had unaltered symptoms after treatment. The results are summarized in *Table 2*. Two patients were operated upon after two and four treatments with alcohol respectively. This was due to the presence of multiple cysts and only moderate regression of cyst size as shown by computed tomography. Both operations were successful.

The mean hospital stay was 2·1 days per treatment.

Discussion

The treatment of non-parasitic liver cysts has been transformed during recent years from an aggressive surgical approach to non-operative treatment. Puncture and evacuation of cyst fluid alone leads to rapid recurrence of the liver cysts. Aspiration with injection of formaldehyde has been performed[7,8] but the relapse rate was high and concerns have been expressed about the potential damage to adjacent liver tissue[9]. Surgical treatment of liver cysts has been recommended, including local excision or formal liver resection[1,6]. In cases with bile-stained cyst contents, internal drainage into the gastrointestinal tract has been performed[10]; however, this can be complicated by cyst infection[3]. In polycystic liver disease, Lin *et al.*[11] described a new approach including excision of the outer wall of the most superficial cysts into which neighbouring deep cysts are successively fenestrated allowing free communication with the peritoneal cavity. This procedure has also proven successful for other investigators[3–5].

Improved radiological and imaging techniques such as ultrasonography and computed tomography can now provide us with detailed information about the size, number and location of liver cysts[12]. These procedures have also increased the number of cysts detected[13]. In the study by Bean and Rodan[14], six patients with non-parasitic hepatic cysts were treated with alcohol instillation into the cyst cavity, in five patients percutaneously under the guidance of ultrasonography and in one patient during laparotomy for a cholecystectomy. No recurrence was seen during a follow-up of 6–18 months. In our series of patients, we combined the use of computed tomography for diagnosis and localization of liver cysts with percutaneous aspiration of cyst fluid and injection of absolute alcohol to sclerose the cysts. The results seem promising, particularly since the procedure has not resulted in severe complications or signs of damage to liver tissue. The patients' discomfort is moderate, the hospital stay is short and the procedure can be repeated if necessary. Furthermore, in the future, when more experience has been gained, many patients can probably be treated on an out-patient basis.

Surgical options in traumatic injury to the extrahepatic biliary tract

P. G. Bade, S. R. Thomson, A. Hirshberg and J. V. Robbs

Department of Surgery, University of Natal, Durban, South Africa

Correspondence to:
Mr S. R. Thomson, Department of Surgery, University of Natal Medical School, PO Box 17039,
Congella 4103, South Africa

A series of 53 patients who sustained extrahepatic biliary tract trauma were analysed to define the role of the various surgical options. Of the 45 patients with gallbladder injuries, 39 were due to stab wounds. Nine of the 45 injuries were repaired by primary suture without complication. Five patients underwent cholecystostomy and all developed biliary fistulae, which resulted in prolonged hospitalization. Cholecystectomy was performed in 31 patients; in retrospect many of these gallbladders could have been preserved because on only eight occasions was the gallbladder extensively damaged. Of eight extrahepatic bile duct injuries, the three partial transections managed by primary repair had a successful outcome, while the five complete transections were managed by a variety of techniques. Delayed diagnosis, failure of operative recognition of the injury and improper management were factors that led to mortality in two patients and prolonged morbidity in another. We conclude that suture repair is the operation of choice for gallbladder stab wounds without extensive injury. Ductal injury must be recognized. Partial transections are best managed by primary repair. Complete transections should be managed by primary duct jejunal anastomosis if the expertise is available.

Keywords: Gallbladder, extrahepatic bile ducts, trauma, operative management

Traumatic injury to the extrahepatic biliary tract is uncommon. The largest reported series consists of 40 patients[1]. Recommendations of operative management that are based on such small numbers of patients remain controversial. Although cholecystectomy is advocated for gallbladder injury[1–4], simple suture repair[5,6] or cholecystostomy[5] has also been advocated. Extrahepatic bile duct injury, though less common, presents a more complex operative problem with a greater potential for morbidity and mortality. At the Natal University affiliated hospitals, individual preference by various trauma surgeons led to the employment of a wide range of surgical procedures in the management of these injuries. This provided us with the opportunity to analyse these options and define their role in extrahepatic biliary tract trauma.

Patients and methods

All patients who sustained extrahepatic biliary tract trauma during the 5-year period 1984–1988 were identified by a computer-aided search using international, diagnostic and operative index codes. Their case records were scrutinized and the following data were extracted: demographic characteristics, mode of injury, clinical presentation, operative findings and treatment, associated injury, length of hospital stay, complications and follow-up. The overall pattern of presentation was analysed collectively but the subsequent management and outcome are discussed separately for the gallbladder and the bile duct injuries. A total of 53 patients (51 men and two women) were included in the series. The median age was 26 years (range 12–58 years).

Results

The 45 gallbladder injuries resulted from 39 stab wounds, five gunshot wounds and one blunt injury due to a motor vehicle accident. There were eight bile duct injuries: three stab wounds, one gunshot wound, and four due to blunt trauma. The blunt duct injuries were caused by a motorbike accident, an industrial accident, an assault, and a kick by a horse.

The presentation of extrahepatic biliary tract injury is shown in *Table 1*. Associated injuries were common and are detailed in *Table 2*. Thirty-five patients had hepatic injury and half the patients had two or more associated injuries. Only six patients had an isolated biliary injury. In two patients who sustained blunt trauma, recognition of their isolated injuries was delayed but did not adversely influence the outcome.

Nearly all the gallbladder stab wounds were through the body or fundus. Nineteen of the gallbladder injuries were described as small incised wounds and 18 were documented as through-and-through wounds. The surgical management and outcome of gallbladder injuries is shown in *Table 3*. Thirty-one patients were managed by cholecystectomy, nine by simple suture repair and five by cholecystostomy. All patients had

subhepatic drainage. Histology of the 31 gallbladders removed revealed extensive injury or intraluminal haematoma in only eight specimens, five of which resulted from gunshot wounds. There were two deaths, both attributable to associated injuries: a cardiac stab wound and a colonic injury. The latter was the only gallbladder injury where delay in diagnosis influenced outcome. Six patients developed a biliary cutaneous fistula; in five this was the direct result of cholecystostomy and in one it was due to a large parenchymal liver laceration. No complications resulted from suture repair of the gallbladder.

The average length of hospital stay is shown in *Table 3*. Patients treated by cholecystostomy stayed in hospital on average 7 more days than patients treated by either cholecystectomy or simple suture repair and this specifically represented the time taken for their biliary fistulae to close.

Table 4 depicts the site of injury, operative management and outcome of bile duct injuries. The three patients who had partial transections were treated by primary repair, with or without a T tube stent. They all recovered and none returned with jaundice or cholangitis.

Five patients had complete transections. Primary repair with T tube stenting and right hepatic lobectomy was the treatment in one patient with a complete transection at the confluence of hepatic ducts and severe liver parenchymal injury due to blunt trauma. He required reoperation to drain a large subhepatic bile collection and later a persistent intrahepatic cutaneous fistula associated with a confluence bile duct stricture was managed by fistulojejunostomy. Despite this he had recurrent cholangitis and died 17 months after initial presentation.

Late recognition of the bile duct injury occurred in the four remaining patients with complete transections. Cholecystjejunostomy with bile duct ligation was employed in the two common bile duct transections caused by blunt trauma. One recovered uneventfully, but, in the other, delay in diagnosis resulted in acute renal failure which complicated his otherwise successful recovery. In another patient, a complete transection due to a gunshot wound through the confluence of the hepatic ducts was not identified at operation because of a hilar liver laceration which was drained. This led to a biliary fistula, stricture, jaundice and a difficult late left hepaticojejunostomy.

The last patient presented to hospital with jaundice and biliary ascites, 3 weeks after an abdominal stab wound. His common hepatic duct transection was treated by hepaticojejunostomy. He subsequently died from septic complications of an anastomotic leak.

Discussion

Extrahepatic biliary tract trauma is usually diagnosed incidentally at laparotomy for penetrating or blunt abdominal injury[2]. The indications for operation are usually peritonitis or shock due to an associated injury. The presentation may be occult and isolated injury is frequently diagnosed late. In this series the delayed presentation of isolated injury was not deleterious to outcome. We and others[1,3] have found that the combination of delay with associated injury contributes significantly to morbidity and mortality. Early recognition is obviously desirable and a high index of suspicion is required so that the diagnosis may be established. Preoperative biliary scintigraphy may delineate the injury[7,8] and intraoperative cholangiography, when feasible, will identify the site of injury[1,9].

Recent reviews and current texts discussing the problem of penetrating gallbladder injury recommend cholecystectomy as the operative management of choice[1-4]. The rationale for cholecystectomy is that there may be contusion to the gallbladder of indefinite extent leading to necrosis, perforation and leakage following repair. The preserved traumatized gallbladder may undergo the cycle of infection, non-function and stone formation. There is no evidence in the literature to substantiate these claims. The rare complication of gallstone formation due to clot retention in the gallbladder as the result of blunt traumatic haemobilia has been described[10].

Options other than cholecystectomy which carry no risk of ductal injury merit serious consideration, in particular preservation of the injured organ. In our series, simple suture repair produced no bile leak or morbidity. The minor degree of gallbladder injury described in the operative record or at histological examination suggests that cholecystectomy could have been avoided in many patients and the gallbladder safely repaired.

Tube cholecystostomy has been recommended in unstable patients with other severe injuries where the surgeon considers cholecystectomy inadvisable[4]. The indication in this series was not intraoperative hypotension but simply the operating surgeon's preference. All gallbladder wounds managed by cholecystostomy were accompanied by prolonged bile leak, and this was the sole reason for prolonging hospital stay.

The most recent reported series advocating cholecystectomy for penetrating gallbladder injury[1,3] consist predominantly of gunshot wounds. In our series, 86 per cent of injuries were caused by stab wounds and in the majority these were incised wounds with minimal contusion, hence our recommendations have a more conservative bias. We advocate gallbladder preservation where feasible for stab wounds, and reserve cholecystectomy for the extensively injured gallbladder which is often due to gunshot injury.

The main factors that dictate the type of treatment in bile duct injury are the nature of the transection, whether partial or complete, and the patient's clinical condition.

Our experience with partial transections was such that they were all amenable to primary suture repair. All three patients had a good outcome and have not returned with complications. Several authors[1,9,11] confirm that simple partial transections treated by primary repair rarely give rise to biliary compli-

Table 4 *Outcome of bile duct injury related to site of injury, presentation delay and operative treatment*

Site	No. of patients	Operation	Outcome
Acute presentation			
Partial transections			
Common hepatic duct	1	Primary repair + stent	Uncomplicated
	1	Primary repair	Uncomplicated
Common bile duct	1	Primary repair	Temporary bile fistula
Complete transections			
Confluence of hepatic ducts	1	Primary repair	Morbidity, reoperations, death
Delayed presentation (>24 h)			
Complete transections			
Confluence of hepatic ducts	1	Drainage	Morbidity, late reconstruction
Common hepatic duct	1	Hepaticojejunostomy	Anastomotic leak, death
Common bile duct	1	Cholecystjejunostomy	Acute renal failure, recovered
	1	Cholecystjejunostomy	Uncomplicated

cations. In one of three partial transections, a T tube stent was used. In this instance, insertion of a T tube through a separate distal choledochotomy across the injury facilitated the repair of a small duct.

In the treatment of complete transections, end-to-end repair leads to a high incidence of stricture formation[11]. This is in part due to compromise to the axial blood supply of the duct caused by the transection and subsequent mobilization required to enable direct repair[12]. Complete transections are thus best managed by biliary enteric anastomosis. Most series[1,3,11] recommend Roux-en-Y duct jejunal anastomosis as providing the best long-term biliary drainage.

In this series and others[9,13] cholecystjejunostomy, the simplest of the operative options, has been employed with at least short-term success. The grounds for recommending this operation are tenuous because there is no long-term follow-up of its use in this setting, and a prospective study has shown that a duct–enteric anastomosis is superior to cholecystjejunostomy in the sustained relief of jaundice[14]. In essence, the gallbladder is an inferior conduit compared with the bile duct.

In the unstable patient where there are other complex injuries, or where the surgeon is inexperienced, an end tube choledochostomy secured to the proximal bile duct creates a controlled external fistula and allows rapid identification at reoperation.

In conclusion it is important to note that while associated injury was the main determinant of outcome in the group of patients sustaining gallbladder trauma, in those patients with bile duct injury, particularly if recognized late, the duct injury itself was pre-eminent in determining outcome. For gallbladder trauma we recommend primary suture repair for incised wounds without extensive injury, and feel it is an under-utilized option. Cholecystostomy has lesser merit as it results in prolonged biliary fistula. Cholecystectomy should be reserved for the more extensive gallbladder injury which usually results from gunshot wounds. In bile duct trauma, early recognition of the injury is essential if serious morbidity and mortality are to be avoided. Partial transections are safely repaired by primary suture. Complete transections are best managed by primary duct jejunal anastomosis if the operator is experienced and the patient stable.

A model of microscopic liver tumour has been developed in the Fisher rat by intraportal injection of $1{\cdot}6 \times 10^{7}$ Walker 256 carcinosarcoma cells. Rats were studied at 2, 4 and 6 days after the inoculation of live Walker cells. A control group received dead Walker cells. No tumour was visible in control groups at 2, 4 and 6 days after inoculation. Similarly in rats injected with live cells no tumour was visible at 2 days after inoculation but at 4 and 6 days the percentage hepatic replacement was (mean ± s.d.) 7·0 ± 2·3 and 27·9 ± 6·80 respectively. The hepatic perfusion index was significantly raised at 4 and 6 days after inoculation of live cells compared with control animals and those receiving viable cells after 2 days inoculation. Portal flow and portal venous inflow were significantly reduced when the hepatic perfusion index increased but hepatic arterial flow did not alter. Changes in the hepatic haemodynamics were accompanied by increases in the portal and splanchnic vascular resistance and an increase in the amount of arteriovenous shunting through the liver. These findings confirm studies that the hepatic perfusion index is useful in the detection of occult liver metastases but that the change is not a consequence of an increase in the hepatic arterial flow.

Keywords: Hepatic perfusion index, hepatic tumours, hepatic haemodynamics

The presence of overt hepatic metastases in patients with colorectal carcinoma is associated with a poor prognosis, most patients dying within 2 years of initial diagnosis[1,2]. Furthermore, approximately 30 per cent of patients with an apparently disease-free liver at the time of their initial laparotomy for colorectal carcinoma develop overt hepatic metastases within 2 years and again the prognosis is poor[3]. It has been suggested that effective therapy for hepatic metastases must be initiated in the early phase of their growth and development. This is supported by the observation that adjuvant portal vein infusion chemotherapy to the macroscopically disease-free liver at the time of resection of the primary colorectal tumour may reduce the incidence of liver metastases[4]. Therefore it is possible that early cytotoxic treatment for hepatic metastases may be effective in patients with occult liver metastases at the time of their initial laparotomy or alternatively where tumour cells have embolized to the liver during the mobilization and resection of the primary tumour.

Current imaging techniques such as computerized tomography, ultrasound scanning and static isotope imaging are not sensitive enough to detect metastases in their early stages of growth and development[5–7]. Recently, interest has focused on the use of dynamic hepatic scintigraphy for the early detection of hepatic metastases[8–12]. Using these techniques Leveson *et al.*[12] have shown that the hepatic perfusion index (HPI), the ratio of the hepatic arterial flow to total liver blood flow determined by dynamic hepatic scintigraphy, is altered in the presence of metastases and that alterations in the HPI predicted the presence of occult hepatic metastases with a sensitivity of 96 per cent.

The mechanism responsible for the alterations in the HPI cannot be established in man because of technical difficulties in accurately measuring the various components of liver blood flow. Therefore this study was undertaken to investigate the changes in the HPI and hepatic haemodynamics during the early stages of growth and development of hepatic tumour in an experimental animal.

Materials and methods

Induction of micrometastases

Walker 256 carcinosarcoma cells were grown in suspension in Williams E (Flow Laboratories Ltd., Rickmansworth, UK) medium supplemented with 5 per cent fetal calf serum at 37°C in a 5 per cent CO_2 atmosphere. Male Fisher rats weighing 290–340 g were anaesthetized with intraperitoneal sodium pentobarbitone ($6\,mg\ 100\,g^{-1}$ body weight). Through a midline incision the portal vein was exposed and 0·2 ml of a suspension of 8×10^{7} Walker cells per millilitre were injected intraportally over 10 s with a 2 Fr gauge needle. The needle was held in position in the portal vein for approximately 30 s after completion of the injection to minimize the risk of spillage of the Walker cells into the peritoneal cavity. Haemostasis was achieved by compression of the portal vein for 30 s. A control group of rats was inoculated similarly with the same number of Walker cells killed by temperature reduction. The laparotomy was closed in two layers and the rats were studied at 2, 4 and 6 days after inoculation of either viable or dead Walker cells.

Radionuclide studies

The method for deriving the hepatic perfusion index in the rat is described in detail elsewhere[13]. Briefly, rats were fasted for 24 h but allowed water *ad libitum* and were anaesthetized with intraperitoneal sodium pentobarbitone. The right carotid artery was cannulated with a 10 cm 2 Fr Portex (London, UK) cannula which was screened into the left ventricle using a Siemans Siremobile (Siemans Ltd., Sunbury-on-Thames, UK) image intensifier. Adequate expulsion of a left ventricular bolus was assessed by the injection of 0·1 ml of sodium meglumine. The rats were then placed supine under an NE 8900 γ camera (Nuclear Enterprises Ltd., Edinburgh, UK) with a 1 cm ($\frac{1}{4}$ inch) pin hole collimator linked to a PDP DEK computer (Digital Equipment Corporation, Maynard, Massachusetts, USA). ^{99m}Tc sulphur colloid (0·04 ml) was injected rapidly as a bolus into the left ventricle and images acquired at 3 frames per second for 30 s and stored on hard disc. A composite image of the first 5 frames of each study was constructed and regions of interest (ROI) were drawn around the left ventricle, right kidney and right lobe of the liver avoiding the superior pole of the kidney and lower border of the lung (*Figure 1*). Time–activity curves were then generated from these ROIs and each curve was subjected to a maximum of three quadratic smooths. Typical time–activity curves for control rats

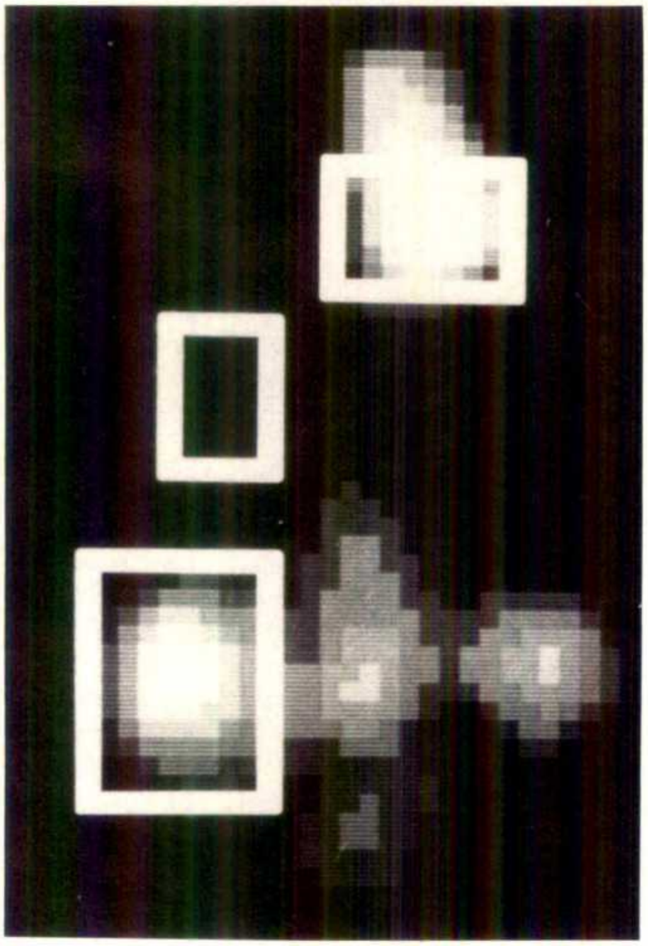

Figure 1 *Composite image obtained by dynamic scintigraphy after the rapid intraventricular injection of 0·04 ml ^{99m}Tc-sulphur colloid showing regions of interest drawn around the heart, liver and right kidney*

are shown in *Figure 2*, and for rats with microscopic hepatic tumours in *Figure 3*.

The HPI was derived from the gradients of the arterial (G_1) and portal phases (G_2) of the liver perfusion curves (*Figure 2*). The left ventricle and right kidney curves were used as the timing reference for the two perfusion phases. The hepatic arterial phase was considered to begin with the start of the kidney arterial phase and extend to the peak of the kidney time–activity curve. The portal inflow phase was assumed to extend from the peak of the kidney curve to either the point of recirculation or to a point at which the kidney time–activity curve reached a plateau.

Haemodynamic measurements

Microsphere technique. Immediately after the completion of the scintigraphic studies the right and left femoral arteries were cannulated using 2 Fr Portex cannulae. The right femoral artery cannula was connected to a Sage 351 (Orien Research Incorporated, Cambridge, Massachusetts, USA) withdrawal pump. The left femoral artery cannula was connected to a physiological pressure transducer for the continuous measurement of arterial blood pressure. A reference blood sample was withdrawn from the femoral artery over a 70-s period. Ten seconds after the start of the blood withdrawal the rats received an intraventricular injection of 60 000–80 000 ^{57}Co Nen-Trac microspheres (New England Nuclear, Stevenage, UK), $16·4 \pm 1$ µm diameter suspended in 0·9 per cent normal saline with 0·01 per cent tween in a volume of 0·4 ml over 20 s.

The animals were killed with an overdose of pentobarbitone 5 min after the microsphere injection. The organs were removed, weighed and the radioactivity counted in a Philips well counter (Pye Unicam Ltd., Cambridge, UK). Cardiac output and liver blood flow were determined by the method of McDevitt and Nies[14]. Portal venous inflow was calculated by adding together the flows to the spleen, pancreas and splanchnic organs. If the blood flow to the right and left kidney was >10 per cent the distribution of the microspheres was not considered to be uniform and the results discarded.

Electromagnetic flowmetry. In further groups of rats inoculated with live or dead Walker cells, a cannula connected to a pressure transducer was placed in the right femoral artery for measurement of arterial blood pressure after the scintigraphic measurements. Through a midline incision the hepatic artery and portal vein were mobilized. Electromagnetic flow probes (Gould Medical Ltd., Lutterworth, UK) were then placed around the portal vein, cranial to its junction with the pancreaticoduodenal vein and around the hepatic artery and zeroed *in vivo* by occluding the vessels distal to the probes. Blood flow in both the portal vein and the hepatic artery were recorded using a Gould Flowmeter (Model SP2202) (Gould Medical Ltd., Lutterworth, UK).

Portal pressure studies. Immediately after measurement of the portal venous and hepatic artery flow, the portal vein was cannulated retrogradely with a 2 Fr paediatric venous cannula 2 cm below the porta hepatis so that the tip of the cannula lay just above the confluence of the splenic and portal veins. The cannula was attached to a pressure transducer to measure portal pressure. No mobilization of the liver was

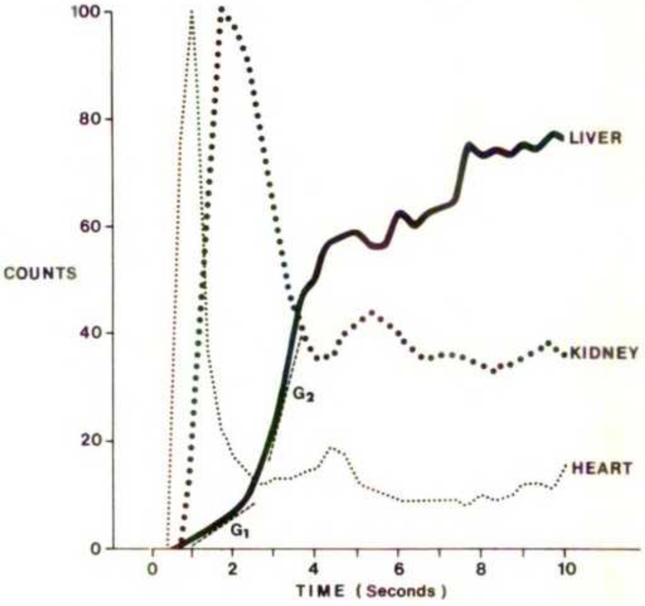

Figure 2 *Typical time–activity curves for control rats showing the derivation of the hepatic perfusion index from the gradients of the hepatic arterial (G_1) and portal venous phases (G_2): hepatic perfusion index = $G_1/(G_1 + G_2)$*

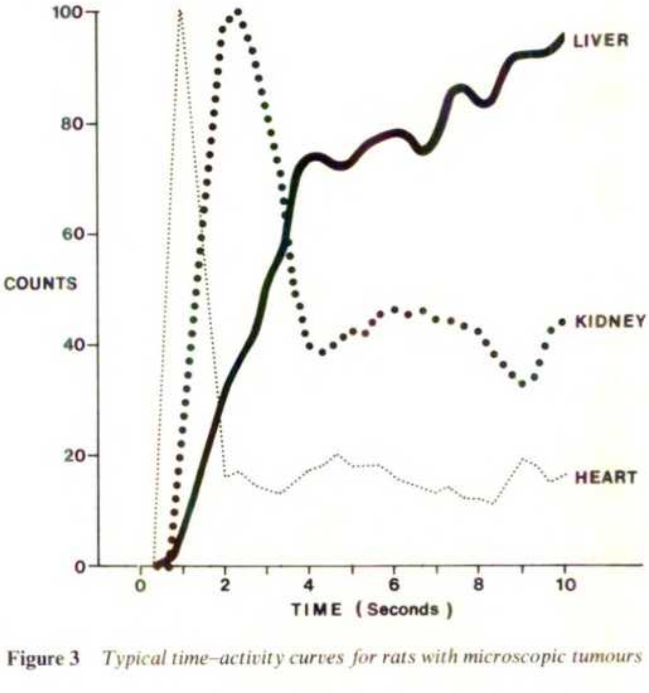

Figure 3 *Typical time–activity curves for rats with microscopic tumours*

required for the procedure and hepatic trauma was avoided during insertion of the cannulae

Splanchnic and portal vascular resistances were calculated from the following equations.

$$\text{Splanchnic vascular resistance (mmHg min ml}^{-1}) = \frac{\text{Mean arterial blood pressure (mmHg)}}{\text{Portal venous flow (ml min}^{-1})}$$

$$\text{Portal vascular resistance (mmHg min ml}^{-1}) = \frac{\text{Portal pressure (mmHg)}}{\text{Portal venous flow (ml min}^{-1})}$$

Measurement of intrahepatic arteriovenous shunting Further groups of tumour-bearing and control rats were anaesthetized with sodium pentobarbitone and through a midline incision the coeliac, hepatic, gastroduodenal and pancreaticoduodenal arteries were exposed The distal gastroduodenal artery was ligated with 7/0 silk at its junction with the pancreaticoduodenal artery, a 10 cm long 2 Fr Portex cannula was inserted via an arteriotomy up to the junction of the coeliac and hepatic arteries and the hepatic arterial pressure was recorded via a pressure transducer. A sodium iodide scintillation detector was then placed over the rat's thorax and screened from the abdomen using a lead shield. Under direct vision with the aid of an operating microscope 1 MBq of 40 μm ^{99m}Tc-macroaggregated albumin in a volume of 0·05 ml was manually injected into the hepatic artery, over a period of 10 s, at physiological pressures using a high pressure liquid chromatography syringe. The amount of radioactivity passing to the lungs was measured by the scintillation counter.

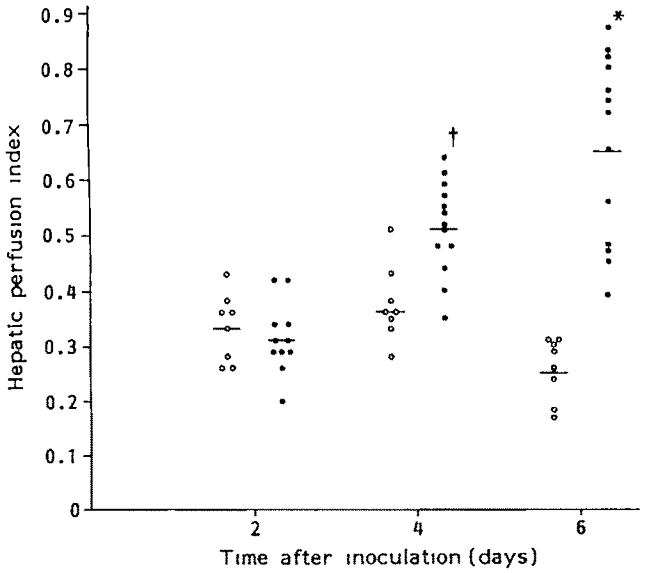

Figure 4 *Hepatic perfusion index values of rats inoculated with live* (●) *or dead* (○) *Walker cells at 2, 4 and 6 days after inoculation* *P<0·01, †P<0·05 (versus *day 2*)

Microscopy. Livers from all rats were fixed in formol saline and sections of 4 μm thickness cut at 1 mm intervals throughout the entire liver Sections were stained with haematoxylin and eosin and the percentage hepatic replacement of the liver was determined using the point sampling technique. Slides were projected on to a large graph paper screen and metastases that fell on the intersects of the graph were counted, allowing accurate quantification of the amount of tumour present.

Statistical analysis

The gradients of the time–activity curves were derived by a least squares analysis for a straight line The comparison of data between groups was achieved by a one-way analysis of variance (ANOVA)

Results

Histopathology

Metastases were not apparent microscopically 2 days after inoculation of the carcinosarcoma cells, only an occasional Walker cell being observed within the portal triads. However discrete micrometastases with a mean diameter of between 100 and 150 μm were present by day 4 after inoculation and these had increased in size by day 6 to 250–350 μm By day 4 the percentage hepatic replacement was 7·0±2·3 (mean ±s.d.) rising to 27·9±6·80 by day 6. No tumour was visible in control animals at any time interval after injection of dead cells.

Hepatic perfusion index

The hepatic perfusion index of control rats receiving dead cells did not change significantly at any time after inoculation. Similarly in rats receiving viable Walker cells, the index at 2 days was not significantly different from controls. There was a significant increase in the HPI at 4 and 6 days in rats inoculated with viable tumour compared with controls and compared with the 2 day stage when no demonstrable tumour growth was evident (*Figure 4*).

Changes in hepatic haemodynamics

No change in portal venous inflow, hepatic artery flow, portal pressure, splanchnic vascular resistance or portal venous resistance was observed in control rats measured by either the microsphere or electromagnetic techniques. The hepatic artery flow did not alter during the growth of the hepatic tumours but the portal venous inflow was significantly decreased at day 4 and at day 6 (P <0·001, ANOVA) compared with the values at day 2 or at any time for control animals injected with dead cells (*Table 1*).

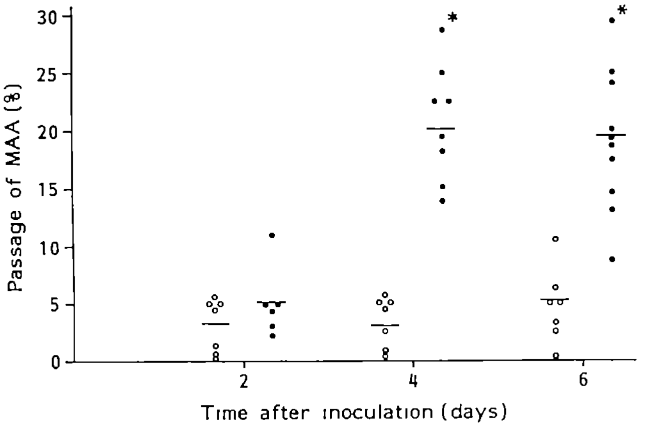

Figure 5 *Percentage passage of microaggregated albumen (MAA) through the liver of rats inoculated with live (●) or dead (○) Walker cells at 2, 4 and 6 days after inoculation.* *P<0·01 (versus *day 2*)

The alterations in hepatic haemodynamics were reproduced by the electromagnetic flow studies which confirmed that there was no change in hepatic artery flow but there was a significant decrease in portal venous flow at day 4 and day 6 after injection of viable Walker cells compared with controls (*Table 2*). The reduction in portal flow at 4 days and at 6 days after inoculation of Walker cells was accompanied by an increase in portal pressure at day 6. Consequently portal vascular resistance and splanchnic vascular resistance were significantly raised at 4 and 6 days (*Table 3*)

Intrahepatic shunting

The passage of microaggregated albumin through the liver did not change in control rats or in the first 2 days after inoculation of viable cells. However at 4 and 6 days there was a significant increase in the passage of microaggregated albumin through the liver compared with the 2-day stage and control animals, indicative of increased intrahepatic shunting with the growth and development of tumour (*Figure 5*).

Discussion

The results of this study in the rat confirm observations in man that the hepatic perfusion index changes during the growth and development of hepatic tumours and may therefore be of diagnostic value in the detection of occult liver micrometastases. It has been assumed that the change in the hepatic perfusion index during the development of hepatic metastases is related to an increase in hepatic arterial flow. This hypothesis was based on observations that liver metastases initially derive their blood supply from the portal vein, but as they increase in size, neovascularization occurs with the formation of both portal and arterial elements. With continued growth of the tumour the portal vessels become compressed and the more tensile arteries provide up to 90 per cent of the tumour's blood supply[15–19]. There have, however, been few detailed studies of the changes in hepatic haemodynamics during the development of liver metastases.

In the present study hepatic tumour was induced in rats by the injection of $1·6\times10^7$ Walker 256 carcinosarcoma cells directly into the portal vein; although this volume of cells may appear to be large it did result in a reproducible model of hepatic tumour in the rat. In order to establish whether an injection of a large number of cells into the liver might influence hepatic haemodynamics by a mechanical effect, the control group animals received the same number of dead cells. Throughout the experiment there were no significant differences in any aspect of haemodynamics in rats inoculated with dead cells at any of the times studied. Furthermore, no alterations in hepatic haemodynamics were observed 2 days after the inoculation of viable cells. Haemodynamic changes were only apparent at 4 and 6 days when liver tumour was histologically evident. It would appear that the relatively large number of cells used in this study to produce liver tumour had no lasting effect on hepatic haemodynamics.

Two haemodynamic methods were used to investigate the change in the hepatic perfusion index during the development of tumours, the use of microspheres to quantify absolute changes in hepatic artery flow and portal venous inflow and electromagnetic flowmetry to determine relative changes in hepatic artery and portal venous flow. The results clearly indicate that the changes in the hepatic perfusion index are a consequence of a decreased portal venous inflow. In all experiments hepatic artery flow did not alter This observation contradicts the hypothesis proposed by Leveson *et al.*[12] who suggested that the alteration of the hepatic perfusion index in the presence of hepatic metastases is due to an increase in total hepatic artery flow. As portal flow decreased with the development of liver tumours, portal pressure increased and consequently splanchnic vascular resistance and portal venous resistance were also signficantly elevated. This change in outflow resistance was reflected by a reduction in intestinal and splenic blood flow and consequently a reduction in portal venous inflow. The decrease in portal inflow with the development of liver tumour could be due to either arteriovenous shunting or a mechanical effect resulting from compression of the portal triad by the tumour. The possibility of a simple mechanical effect of the tumour cannot be discounted, but is difficult to demonstrate experimentally

In the present study increased passage of ^{99m}Tc microaggregated albumin through the liver occurred at 4 and 6 days after inoculation of viable Walker cells suggesting that the increase in portal resistance could be due, at least in part, to the development of new arteriovenous shunts within or surrounding the tumours rather than at pre-existing presinusoidal arterioportal communications[18]. The presence of unidirectional arterioportal shunting has previously been reported by Geumei *et al.*[20] and casting studies have demonstrated that neovascularization is well developed by the time metastases have grown to 1 mm in diameter[21]. Of particular relevance to the present study is the observation that viable tumour is only present 4 days after direct injection of Walker cells into the liver parenchyma. At this stage of development, blood vessels supplying the tumour display a remarkable tortuosity and distribution and by day 6 there is evidence of an increased blood supply to tumour, the new vessels being characterized by their irregular size and the presence of anastomotic connections between them

This study confirms previous observations in man that the hepatic perfusion index does alter with the presence of micrometastases. The change in the index is secondary to a reduction in portal venous inflow consequent on an increased portal vascular resistance Hepatic artery flow does not increase during the early stages of hepatic tumour development but an increase in arterioportal shunting occurs even in tumours as small as 150 μm in diameter. Alteration in the hepatic perfusion index appears, therefore, to be a sensitive method for the early detection of hepatic metastases before they are large enough to be diagnosed by conventional imaging techniques It is possible that micrometastases may be more sensitive to cytostatic therapy than larger liver secondaries and hence early detection would be of advantage. Clearly, further studies are required to substantiate this hypothesis.

Direct retroperitoneal approach to necrosis in severe acute pancreatitis

P.-L. Fagniez, N. Rotman and M. Kracht

Department of General Surgery, Hôpital Henri Mondor, 51 Avenue du Mal de Lattre de Tassigny, 94010 Créteil, France

Correspondence to. Professor P.-L. Fagniez

From 1981 to 1987, 40 patients with severe acute pancreatitis were operated on using a direct retroperitoneal approach, 22 primarily and 18 after a first operation performed through another incision. The severity of the disease was assessed by Ranson's bioclinical and computed tomography scan scoring systems. The retroperitoneal approach consisted of a left lateral incision, just anterior to the 12th rib, allowing direct access to the pancreas and a complete manual exploration of the gland and peripancreatic spaces. All patients but one were operated on for infected necrosis. The overall mortality rate was 33 per cent but was lower in the patients operated on primarily through a direct retroperitoneal approach (18·2 per cent). Twenty patients (50 per cent) developed a local complication (haemorrhage, colon fistula and/or necrosis). The direct retroperitoneal approach permits the removal of necrosis and several reoperations without the risk of large wound dehiscence and does not preclude the extension of the incision to a subcostal incision when necessary.

Keywords: Severe acute pancreatitis, surgical treatment

Although necrosis is found in only 4–16 per cent of all patients with acute pancreatitis, most of the patients with a necrotizing form of pancreatitis will require surgery in the course of the disease[1–3]. The rationale for the surgical drainage of pancreatic necrosis is (1) the early removal of activated pancreatic enzymes, endotoxins and vasoactive products responsible for multiple organ failure[3] and (2) the avoidance of infection of necrosis which is a major cause of death and which has been reported to occur in almost 80 per cent of patients surviving longer than 7 days[4].

The extent of the surgical procedure in necrotizing pancreatitis has been widely debated over the years; various attitudes have been proposed from extensive pancreatectomy[5–8] to limited débridement of necrosis[1–3,9,10]. We report here our experience of the surgical treatment of severe acute necrotizing pancreatitis using a direct retroperitoneal approach.

Patients and methods

Patients

From 1981 to 1987, 40 patients with severe acute pancreatitis were operated on using a retroperitoneal approach. These patients represent 27·2 per cent of the patients hospitalized for acute pancreatitis (during the study period 147 patients were treated in our hospital for mild acute pancreatitis). There were 30 men and 10 women. Their ages ranged from 26 to 80 years (median 46 years). The main cause of pancreatitis was alcohol (26 patients). Nine patients had pancreatitis related to gallstones, three patients had postoperative pancreatitis, one had a carcinoma of the head of the pancreas and in one case the aetiology of the pancreatitis could not be determined. The severity of the pancreatitis was assessed by the Ranson criteria score in 31 patients[11]. The median value for the bioclinical criteria was four: eight patients had three prognostic signs, seven patients had four, seven patients had five, five patients had six and one patient each had one, two, seven and eight prognostic signs. In nine patients, referred from other hospitals, one or more of the bioclinical criteria were missing and the severity score could not be established. All the patients had at least one contrast-enhanced computed tomography (CT) scan before operation. CT scans were performed using a Somatom Siemens SF (Siemens Medical Engineering Group, Erlangen FRG) with a 4·5 s scan time and a section thickness of 10 mm. Patients were given 1 litre water-soluble contrast medium orally or through a nasogastric tube before the examination. CT scans were performed before and after an intravenous bolus injection of 60 ml contrast medium. The average number of CT scan examinations per patient (pre- and postoperatively) was four. CT scans were graded according to Ranson's classification[12]. Thirty-nine patients had a grade E (two or more fluid collections) contrast-enhanced CT scan; one patient was grade D (one fluid collection). Percutaneous aspiration of peripancreatic fluid was performed under CT scan guidance in ten patients at our institution. In all cases it yielded fluid for bacteriological analysis.

Twenty-four patients were referred from other institutions, 18 after being operated on. Twenty-two patients (six referred and 16 hospitalized primarily at our institution) were operated on primarily in our hospital.

Clinical management

All patients were admitted to an intensive care unit. Medical treatment included nasogastric suction, total parenteral nutrition and cardiac monitoring. Antibiotics were administered only to patients with proven bacterial infection. Mechanical ventilation was necessary for more than 48 h in 19 patients. Peritoneal dialysis was performed in ten patients presenting with hypotension (< 100 mmHg) or severe abdominal pain with diffuse guarding at the time of admission. The median duration of dialysis was 1·9 days. Eight patients were treated by drainage under CT guidance. Percutaneous drainage was performed before operation in five patients and in three patients for residual peripancreatic collections after a first operation. The aim of the percutaneous drainage was to avoid operation in patients with homogeneous, low density collections which were thought to consist of infected fluid without debris. Surgery was considered in three circumstances: (1) deterioration of renal, pulmonary or cardiac function despite medical treatment (16 patients); (2) septic shock unexplained by a source of infection other than an abdominal abscess (14 patients), (3) the recovery of infected fluid under CT scan guidance and/or the failure of percutaneous drainage (ten patients).

Surgical technique

The retroperitoneal approach to the pancreas was conducted through a left lateral subcostal incision, 10–15 cm in length, located just anterior to the 12th rib. The peritoneal attachments of the upper part of the descending colon were then divided allowing direct access to the pancreas (*Figure 1*). In four patients with collections and necrosis developing in the right mesocolon and the right pararenal spaces, a similar right subcostal incision was used; in these cases the retroperitoneum was reached after mobilization of the ascending colon. The whole pancreas, from tail to head, as well as the peripancreatic spaces were explored by manual palpation. All pancreatic and peripancreatic necrosis and fluid collections were removed by blunt dissection and the apparently healthy part of the pancreas was left in place. The retroperitoneum was drained by one or two tube drains. In 14 patients continuous irrigation of the retroperitoneum was performed by means of

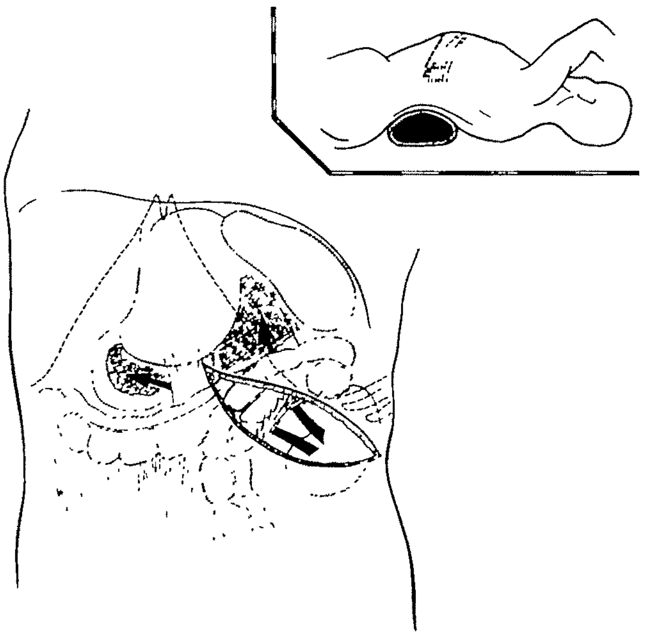

Figure 1 *A left posterior subcostal incision (top, right) allows a direct retroperitoneal approach to the pancreas after division of the attachments of the descending colon (bottom, left)*

a double-lumen nasogastric suction tube. The other patients had discontinuous irrigation by drains. The solution used for lavage was a 10 per cent solution of povidone-iodine

Six patients had a cholecystectomy, two patients had a cholecystectomy with common bile duct drainage, and five had a cholecystostomy. These procedures were performed at the first operation and mainly in patients referred from other institutions. Only two patients admitted primarily to our hospital underwent a biliary procedure (one cholecystostomy and one cholecystectomy).

Results

The limited retroperitoneal approach through a left lateral subcostal incision allowed complete exploration of the pancreas in all patients. Thirty-five patients (88 per cent) had pancreatic and peripancreatic necrosis. The parenchymal necrosis was located in most patients at the periphery of the gland, leaving a healthy central part. Only one patient had complete necrosis of the head of the pancreas. In all patients but one the necrosis was infected. The most common organisms cultured were Gram-negative bacteria (*Tables 1* and *2*). Four patients had infected fluid collections with minimal necrosis. One patient had a sterile fluid collection. Infection was present at the first operation in 18 patients. In 21 patients infection was disclosed at the second operation. in ten cases it was a superinfection as the material yielded from the first operation was sterile while in 11 cases bacteriological findings from the first operation were not available. At the time that infection was diagnosed only two patients had a colonic fistula. In three patients the presence of fluid collections and necrosis in the right pararenal anterior space and right mesocolon required further débridement through a right limited incision.

The average number of operations per patient was 3·6 (range 1–9). Eight patients had only one operation. The median timing of the first operation was 14 days after the onset of the disease for the patients operated on at our hospital. Patients operated on before referral underwent their first operation after a median time of 3 days

Five patients developed general complications without local complications. Twenty patients (50 per cent) developed local complications (*Table 3*). Haemorrhage occurred in eight patients. In five cases it was limited to a diffuse oozing from the retroperitoneum and was treated successfully by packing. Three patients had major haemorrhage resulting in cardiocirculatory failure in the operating room. Packing stopped the haemorrhage in one case. In the two other patients the limited incision had to be extended to a bilateral subcostal incision to control the haemorrhage. One patient had a splenectomy for a spontaneous splenic haematoma.

Left colonic fistula, related to the repeated mobilization of the left colon, developed in eight patients and was treated by right transverse colostomy This was closed after healing of the fistula had been confirmed by barium enema. In one patient the fistula did not close despite the colostomy, and it was closed surgically. One patient had a pancreatic fistula which healed spontaneously after 6 months. One patient had a gastric fistula but died of multiple organ failure with no treatment of the

fistula. One patient had a major haemorrhage from a posterior duodenal ulcer which required surgery Two patients had a transverse colon necrosis and one had a necrosis of the right colon related to an anterior extension of the inflammatory process with thrombosis of the colonic vessels.

Thirteen patients died (33 per cent) Two patients died from complications of mechanical ventilation (acute airway obstruction and tracheal necrosis) Two patients died from pulmonary embolism with no progressive pancreatitis. One patient died from massive haemorrhage from the portal vein which could not be controlled. One patient died from a carcinoma of the head of the pancreas which was the cause of the pancreatitis; in this patient the inflammatory process had subsided at the time of death. Seven patients died from multiple organ failure The median time of death was 58 days. Only four patients out of the 22 operated on primarily at our institution died (18·2 per cent); one of these patients died from pulmonary embolism.

Three out of seven patients with multiple organ failure died without continuing pancreatitis from septicaemia due to *Candida albicans*. The other four died with progressive necrotizing pancreatitis. The overall hospital stay for survivors and non-survivors was 70 ± 38 days. Nine patients developed a wound hernia which was repaired 6–12 months after hospital discharge. Only two patients became diabetic and required permanent insulin treatment.

Discussion

Necrotizing pancreatitis is characterized by haemorrhagic necrosis of the gland and by fatty and haemorrhagic necrosis of the peripancreatic spaces Most often the necrotizing process remains enclosed in the retroperitoneum and develops to the left and anteriorly. It seemed to us that a direct retroperitoneal approach to the pancreas would be the best way to remove necrosis and to achieve adequate direct drainage of collections and necrosis[13] This type of approach allows complete exploration of the gland and peripancreatic spaces but precludes a formal pancreatectomy. Some authors advocate extensive pancreatectomy[5–7] in order to limit the general and local complications of the disease, but these procedures carry a high mortality rate (30–50 per cent) and do not completely prevent the occurrence of pancreatic abscesses[6,14]. On the other hand, there is a trend towards a restriction of the indications of surgery[13,15–17]. However, in a deteriorating patient with signs of severe sepsis or multiple organ failure unexplained by extra-abdominal causes, surgery cannot be postponed.

The advantages of a retroperitoneal approach are multiple it can be used for several reoperations without the disadvantages of a large wound dehiscence, it can be performed in patients previously operated on through a transperitoneal approach, it allows the scooping out of all necrotic and purulent material, and it does not preclude the extension of the incision to a right or bilateral subcostal incision. This situation was met in five patients: one with massive haemorrhage, one with haemorrhage from the portal vein and transverse colon necrosis, one with a bleeding duodenal ulcer and two with colon necrosis Some authors advocate wide exploration of the entire abdomen in order not to overlook a necrotic collection[10,16]. In our series, CT scanning, which was performed in every patient, allowed precise preoperative localization of the necrotic collections[13].

The two drawbacks of our method are colonic fistulae due to the repeated mobilization of the descending colon and wound hernias We observed eight colonic fistulae attributable to the surgical procedure This complication occurred at the beginning of our experience because of insufficient dissection of the left colon attachments. No patient died from this complication. Wound hernias are caused by incomplete closure of the wound, the drains being brought out through the incision. Nine patients developed a wound hernia which was repaired 6–12 months after hospital discharge.

Another theoretical disadvantage of this method is that no biliary procedure can be performed; 85 per cent of the biliary procedures in our patients were performed in other institutions. Actually, there was no evidence that the biliary procedures improved survival It seems that once severe acute pancreatitis is initiated, the prognosis relies on its evolution, and that the removal of common bile duct stones may not really influence survival. This is in accordance with the views of Ranson[18] who showed that the mortality rate in acute pancreatitis diminishes when biliary surgery is postponed. In the case of impacted stones, the best approach now appears to be endoscopic retrograde sphincterotomy[19].

In 97 per cent of our patients retroperitoneal infection was present. Infection was diagnosed successfully by percutaneous aspiration in the ten patients on whom it was performed. The high frequency of infection in our series is probably due to the timing of surgery. Warshaw and Gongliang[16] have shown that pancreatic abscess usually appears 2–3 weeks after the onset of the disease. In a retrospective autopsy study, Renner *et al.* showed that in patients surviving more than 7 days, infection was present in 80 per cent of cases[4]. The high rate of infected necrosis may explain the overall mortality rate of 33 per cent that we observed, as infected necrosis increases the mortality rate[20]. It is, however, noteworthy that the mortality rate was 18·2 per cent in the patients operated on primarily by a limited incision. We conclude that surgical treatment of severe acute pancreatitis through a direct retroperitoneal approach is a relatively safe and simple method of removing necrosis and infected fluid collections.

Contrast-enhanced abdominal computed tomography scanning and prediction of severity of acute pancreatitis: a prospective study

One hundred and fifty-two patients were admitted to a single hospital with a diagnosis of acute pancreatitis during a 31-month period. Of these, 126 patients had contrast-enhanced abdominal computed tomography (CT) scans within 72 h of admission; 92 of these attacks were clinically mild, 34 were clinically severe. A single consultant radiologist reported the scans 'blind' and noted whether pancreatic enhancement was normal, increased or decreased, and whether there was loss of peripancreatic tissue planes. The maximum anteroposterior measurement of the pancreatic head and body were multiplied together to produce a 'pancreatic size index' (cm^2). Significantly more patients with severe attacks had decreased pancreatic enhancement (79 versus *58 per cent,* $P = 0{\cdot}01$*) and loss of peripancreatic tissue planes (82* versus *54 per cent,* $P = 0{\cdot}006$*). The median (range) pancreatic size index for clinically severe attacks was 12·8* cm^2 *(3·0–52·5), and for mild attacks was 6·0* cm^2 *(1·1–23·4),* $P < 0{\cdot}0001$*. Modified Glasgow criteria had a sensitivity of 85 per cent and specificity of 79 per cent for clinically severe attacks. A pancreatic size index of* $\geqslant 10$ cm^2 *had a sensitivity of 71 per cent and specificity of 77 per cent for clinically severe attacks. In conclusion, although there were highly significant differences between the clinically severe and mild groups with respect to pancreatic enhancement, peripancreatic tissue planes and pancreatic size indices, these CT criteria did not improve on modified Glasgow criteria for prediction of disease severity.*

The mortality rate of acute pancreatitis in the UK is about 10 per cent[1-4]. The ability to predict those patients whose pancreatitis is going to follow a severe course allows selective intensive therapy and, in the case of gallstone pancreatitis, a reduction in morbidity and mortality rate by endoscopic sphincterotomy[5]. The methods used to predict severity have included clinical judgement[6], single[7] or multiple[8] biochemical criteria, and peritoneal fluid analysis[9]. Although it has been demonstrated that abdominal computed tomography (CT) scanning is valuable in the diagnosis of pancreatitis[10] and its local complications such as pancreatic necrosis[11,12], abscess[13,14] and pseudocyst[15], there have been few prospective studies[16-22] concerning the prediction of severity by abdominal CT. Those studies that have been performed have examined selected patients, not all of whom have been scanned early in the course of their disease. The CT criteria have been complex and no studies have produced sensitivities and specificities of these criteria for severe attacks.

The purpose of this prospective study was to obtain an abdominal contrast-enhanced CT scan within 72 h of admission on all patients with acute pancreatitis and, having determined the CT criteria that best predicted the clinical severity of the disease, to compare them with an established clinicobiochemical prognostic system.

Patients and methods

During the period May 1984–December 1986 patients admitted to the Leicester Royal Infirmary with acute pancreatitis were referred for contrast-enhanced CT scanning. The diagnosis was based on a serum amylase > 1000 units/l (Phadebas method) in the presence of a compatible clinical picture. The predicted severity of the attack was determined within 48 h using eight of the Glasgow criteria, including age > 55 years but excluding a serum alanine transaminase > 200 units/l[23] (*Table 1*).

All scans were performed within 72 h of admission on a GE 8800 scanner (General Electric, Milwaukee, USA) and reported 'blind' by a single consultant radiologist. A plain scan was followed by a contrast-enhanced scan taking 10 mm contiguous cuts during an intravenous infusion of 100 ml Niopam 370 (Merck, Alton, UK). Pancreatic enhancement was defined as increased, normal or decreased, relative to the enhancement of the liver and spleen. It was noted whether there was loss of peripancreatic tissue planes, and the maximum anteroposterior measurements (in centimetres) of the pancreatic head, body and tail were recorded. These measurements were taken opposite the right-hand border of the lumbar vertebrae, the left-hand border of the aorta and the left renal hilum respectively. The measurements from 50 scans were repeated by an independent observer in order to determine their reproducibility. A clinically severe outcome from pancreatitis was defined as death or a major local or systemic complication. The different

Pneumonia	5
Renal failure	4
Pseudo-obstruction	1
Duodenal obstruction	1
Disseminated intrasvacular coagulation	1

Numbers in parentheses indicate deaths

CT parameters and the modified Glasgow criteria were compared with respect to their ability to predict the clinical outcome

Statistical analysis

Continuous variables were analysed by the two-tailed Mann–Whitney U test. Discrete variables were analysed by the χ^2 test with Yates' correction when the expected number of observations was small. Statistical significance was assumed to be $P<0·05$ Sensitivity and specificity were calculated as described by McNeil *et al* [24]

Results

During the period of the study, 152 patients were admitted to the Leicester Royal Infirmary with a diagnosis of acute pancreatitis. Of these, 126 patients (83 per cent) had abdominal contrast-enhanced CT scans within 72 h of admission and 26 patients (17 per cent) were not scanned. The clinical severity of those patients who were and were not scanned is given in *Table 2*. The age and sex of the 126 patients who had CT scans and the aetiology of their attacks is given in *Table 3*. None of these 126 patients was subsequently found to have a diagnosis other than that of acute pancreatitis. The major complications of those patients with clinically severe attacks are given in *Table 4*. There were six deaths, and nine patients (7 per cent) required operations for local complications of pancreatitis.

The differences between the clinically mild and severe groups with respect to pancreatic enhancement, peripancreatic tissue planes and pancreatic size measurements are given in *Tables 5* and *6*. When 50 pancreatic size measurements were repeated by a second observer the median (range) difference between his measurements and those of the original radiologist was 0·5 cm (0·0–1·4) ($P=0·8$, Wilcoxon matched-pairs signed-ranks test).

The product of the pancreatic head and body measurements (which we called the 'pancreatic size index') provided the best sensitivity and specificity for clinically severe attacks. The sensitivities and specificities of various CT criteria, modified Glasgow criteria, and a combination of the two for severe attacks are given in *Table 7*. There were 11 patients who developed local complications of their pancreatitis (six pancreatic abscesses, five pseudocysts); *Table 8* compares the CT findings in these 11 patients with the findings in the 115 patients who did not develop local complications. A pancreatic size index of $\geq 10\,\text{cm}^2$ had a sensitivity of 73 per cent (8/11 patients) and specificity of 68 per cent (78/115 patients) for predicting the development of local complications.

Discussion

This is the first report from the UK of abdominal enhanced CT and the prediction of severity in acute pancreatitis. Previous studies from the USA[19–21], FRG[16–18] and Switzerland[22] have

examined selected patients; the high incidence of alcoholic pancreatitis in the USA[25,26] makes it difficult to relate the results of studies performed there to the situation in the UK. Although a recent prospective study from Geneva[22] has scanned a population with a similar incidence of gallstone pancreatitis (55 per cent) to that seen in the UK (44–57 per cent)[4,8,23,27] the incidence of pancreatic abscess (17·6 per cent) suggested 'that a relatively high proportion of severe pancreatitis' was included. The age–sex distribution, aetiology of pancreatitis, mortality rate (5 per cent), incidence of clinically apparent pseudocyst (4 per cent) and abscess (5 per cent) in our study were similar to those of other studies of pancreatitis in the UK, confirming that the patients in this study were not selected. The proportions of patients with severe attacks amongst those who had and did not have CT scans were not significantly different, indicating that the patients who were scanned had not been selected in terms of severity. There were inevitably significantly more deaths amongst the group of patients who were not scanned because those who were moribund on admission were not referred for CT scanning.

Eighty-three per cent of patients admitted with acute pancreatitis during the study period had abdominal enhanced CT scans within 72 h of admission. Although it would have been preferable to scan all patients within 24 h of admission, this was not possible because we were unable to scan patients during the weekend period. It is important to scan patients early in the course of their disease not only because selective intensive therapy can then be implemented at an early stage but also because it has been shown that the concordance between CT findings and clinical staging increases from 71 per cent at 72 h to 85 per cent at 6 days[28] This means that CT criteria derived from scans performed after 72 h will inevitably produce high sensitivities and specificities for severe attacks since the local disease process is well established by this time.

The design of this study was prospective and the CT criteria were chosen before the study commenced. The only retrospective analysis was the derivation of the 'pancreatic size index' which best predicted severity The value of this pancreatic size index for the prediction of severity does therefore need to be confirmed in a prospective study. We chose relatively simple CT criteria because we felt that a complex grading system would not be applicable to general surgical practice.

It has been demonstrated both experimentally[29,30] and in patients with alcohol-induced pancreatitis[31,32] that there is reduced contrast enhancement of the pancreas in those cases that develop severe attacks. We assessed pancreatic enhancement visually because we wished to estimate overall pancreatic enhancement rather than the mean value of selected areas as measured by Houndsfield units[30]. Similarly it has been reported that extrapancreatic spread of oedema or 'phlegmon' correlates with morbidity and mortality rates from acute pancreatitis[16–18,20–22,33–35]. Extrapancreatic fluid collections are prone to secondary bacterial infection and are recognized CT risk factors for the development of pancreatic abscess[13,21]. These fluid collections have not been shown to correlate with overall prognosis[14,16,36] and we did not include them in our CT criteria. The measurement of extrapancreatic oedema has been complex in previous studies[17,18,22]. We simplified the interpretation of the CT scans by recording whether or not there was loss of peripancreatic tissue planes[37].

At the time that this study commenced there were no reports of the prognostic significance of the degree of pancreatic parenchymal swelling. Becker *et al* [18] and Takada *et al.*[37] have since shown that the degree of pancreatic swelling is correlated with clinical severity. Whereas Becker *et al.*[18] recorded pancreatic size by comparing the sagittal diameter of the pancreas with that of the adjacent vertebral body, we used measurements of pancreatic head, body and tail taken from the CT scans.

Although there were significantly more patients with severe pancreatitis who had loss of peripancreatic tissue planes and decreased pancreatic enhancement, the specificity of these criteria for severe attacks was too low to be of clinical value (*Table* 7). These findings are similar to those of Grabbe *et al* [16]. The differences in pancreatic size measurements between the mild and severe groups were highly significant. The CT size index which best predicted the severity of pancreatitis was the product of the head and body measurements, or 'pancreatic size index'. A pancreatic size index $\geqslant 10\,cm^2$ had a sensitivity of 71 per cent and specificity of 77 per cent for severe attacks (*Table* 7). This compared with a sensitivity of 85 per cent and specificity of 79 per cent using modified Glasgow criteria. The combination of a pancreatic size index $\geqslant 10\,cm^2$ and/or modified Glasgow criteria produced a sensitivity or specificity which was too low to be of any clinical value (*Table* 7).

It has been suggested by Ranson *et al.*[13] that early imaging of the pancreas by CT can identify a group of patients with an increased risk of pancreatic abscess. Vernacchia *et al.*[14] have not been able to reproduce Ranson's results and have suggested that CT should be restricted to patients who have a clinically suspected surgical complication. We have found that although CT is sensitive (73 per cent) for the prediction of the development of local complications, the specificity is too low (68 per cent) to be of any clinical value. We would stress that the purpose of this study was to determine the value of an early contrast-enhanced CT scan for the prediction of overall clinical severity. Our results are not comparable to those of Block *et al.*[11] and Kivisaari *et al* [12] who have used high-dose, rapid-bolus intravenous contrast infusions in conjunction with dynamic CT scanning in order to detect pancreatic necrosis in patients with established severe pancreatitis

It is difficult to make meaningful comparisons between the results of this study and those of other prospective studies because previous reports have examined patients with a different spectrum of disease to that seen in the UK (*Table* 9). We would, however, agree with Grabbe *et al* [16] that a contrast-enhanced scan does not improve on the prognostic value of a plain scan We have also noted that in certain cases the CT prediction of severity may be markedly different from the clinical course of the disease[16,19,22]. We found that the sensitivities and specificities of CT criteria for the prediction of severe pancreatitis were similar to those of modified Glasgow criteria and for economic reasons we would not recommend routine CT scanning of all patients with acute pancreatitis. It has been suggested that CT should be reserved for patients who demonstrate persistent toxicity[13], or restricted to those who are predicted severe by multiple biochemical criteria[22,38–40]. It has yet to be determined whether or not these policies will reduce the morbidity or mortality of patients with established or biochemical predicted severe attacks It has, however, been shown that abdominal CT, with contrast enhancement[11], is valuable in the assessment of established local complications of acute pancreatitis[41–43] and that it is superior to ultrasonography in this situation[10].

In conclusion, although it has been shown by other authors that contrast-enhanced CT is valuable in the diagnosis and

Case report

Br. J Surg. 1989, Vol. 76, March, 272

Superior mesenteric vein thrombosis caused by Yersinia pseudotuberculosis

R. C. Stuart, A. L. Leahy, M. T. Cafferkey* and R. B. Stephens

*Departments of Surgery and *Microbiology, St James's Hospital, St. James's Street, Dublin 8, Ireland*

Correspondence to. Mr R B Stephens

Since the first isolation of *Yersinia pseudotuberculosis* from the mesenteric lymph node of a patient who had the clinical picture of acute appendicitis[1] many reports of mesenteric lymphadenitis secondary to *Y. pseudotuberculosis* have appeared. *Y pseudotuberculosis* may also cause intestinal ulceration, peritonitis and septicaemia, sometimes with a fatal outcome.

We report a case of massive mesenteric lymphadenitis caused by *Y. pseudotuberculosis*, resulting in superior mesenteric vein thrombosis and small intestinal gangrene.

Case report

A previously healthy 39-year-old man presented with a 1-week history of crampy central abdominal pain, watery diarrhoea and vomiting. On examination he was ill, febrile, and his abdomen was distended and tender to deep palpation Other findings, including rectal examination, were normal. Initial investigations revealed a neutrophil leucocytosis

On the evening of admission laparotomy was performed The entire mesentery was thickened with massive lymph node enlargement. Of the necrotic small intestine 6 cm were resected, commencing at the ligament of Treitz. The patient was anticoagulated with intravenous heparin for 5 days followed by oral warfarin for 3 months. Improvement was rapid, and he was discharged 14 days after surgery Some 5 years later the patient remains well with no recurrence or progression to inflammatory bowel disease.

Histological examination revealed transmural necrosis and marked congestion There was extensive venous thrombosis and the vessels in the area of necrosis demonstrated prominent acute mural inflammation secondary to ischaemia rather than to a primary vasculitis. The lymph nodes were reactive and congested with no evidence of lymphoma or malignant histiocytosis

Y. enterocolitica and Y pseudotuberculosis serology were performed Antibody to *Y pseudotuberculosis* was present at a titre of 640. After absorption with *Salmonella enteritidis* the residual *Y pseudotuberculosis* titre was 160 This was considered as evidence of infection with *Y pseudotuberculosis* as the upper limit of the normal range is a titre of 80 At 6 weeks follow-up the *Y pseudotuberculosis* titre (absorbed) was 80

Discussion

Two basic forms of the *Y. pseudotuberculosis* infection have been described: an often fatal septicaemia and a more benign mesenteric lymphadenitis[2]. The benign mesenteric lymphadenitis is self-limiting, is not associated with underlying diseases and resolves without antibiotic intervention Systemic yersinosis requires antibiotic therapy and is associated with underlying illness such as chronic liver disease, siderosis, and the administration of desferrioxamine.

Life-threatening complications of mesenteric lymphadenitis are rare. Venous thrombosis caused by *Y pseudotuberculosis* has not been previously reported. One case of small bowel gangrene caused by *Y. enterocolitica III* has been cited[3]. The mechanism of the venous thrombosis remains unproved. The histological pattern of the vessels in our case and that of Leino *et al.*[3] was secondary to ischaemia rather than a primary vasculitis. The most likely cause of the obstruction of the superior mesenteric vessels was extraluminal compression by the massive lymphadenopathy

Proctocolectomy and ileoanal pouch anastomosis without conservation of a rectal muscular cuff

The technique of proctocolectomy and formation of an ileal reservoir with ileoanal anastomosis is well described. It is believed that the conservation of a rectal muscular cuff is necessary for continence but no data are available to support this contention. The aims of this study were to describe the clinical and physiological aspects of continence after proctocolectomy and ileal J pouch anastomosis without conservation of a rectal muscular cuff. Eighteen consecutive patients (mean age 37·3 years, 16 ulcerative colitis, two familial polyposis) who underwent proctocolectomy and ileoanal anastomosis on the dentate line were studied 6 months after closure of the loop ileostomy. The 18 patients and eight controls underwent: (a) anal manometry; (b) determination of maximum tolerable volume (MTV); (c) liquid continence test (infusion of NaCl at 60 ml/min for 25 min) with simultaneous measurement of ileal reservoir pressure. The volume evacuated during 5 min after the continence test was also measured. The frequency of bowel actions was (mean ± s.e.m.) 5·3 ± 0·4 per 24 h (nocturnal 1·14 ± 0·26). Seventeen of 18 patients (94 per cent) had normal continence and defaecation; one patient was incontinent. A decrease in resting anal canal pressure (102·5 ± 4 versus *47·5 ± 6 cmH_2O) was observed after ileoanal anastomosis. A rectoanal inhibitory reflex was elicited in one of the 18 patients (6 per cent). Patients were able to retain 1023 ± 68 ml saline during the liquid continence test. The percentage evacuation of the ileal reservoir was 61 ± 4·5 per cent. Correlations were found* ($P = 0{\cdot}05$) *between daily stool frequency and the volume of saline retained during the liquid continence test. It is concluded that conservation of a rectal muscular cuff is not necessary for the achievement of good clinical results.*

Proctocolectomy with ileal pouch–anal anastomosis for the treatment of chronic ulcerative colitis and familial polyposis coli offers an alternative to conventional ileostomy or ileorectal anastomosis[1].

All the surgical techniques proposed in the past have been based on the theoretical assumption that the last 2 or 3 cm of rectal muscular cuff are essential for the maintenance of adequate anal continence, but no data are available to support this concept. More recently, proctocolectomy with total removal of the rectum followed by ileal pouch anastomosis to the dentate line has been described[2–5]. The aim of this study was to determine: (a) the anal and the ileal reservoir function after colectomy, total removal of the rectum and ileal pouch anastomosis; and (b) which functional features of the anal sphincter and ileal pouch are responsible for poor or good clinical results.

Patients and methods

Patients

Eighteen consecutive patients who had undergone proctocolectomy with ileal pouch–anal anastomosis for chronic ulcerative colitis ($n = 16$) or familial polyposis coli ($n = 2$) were studied. The group consisted of eight men and ten women aged from 21 to 73 years (mean ± s.e.m., 37·3 ± 2·6 years). All medication was stopped for at least 4 days before the study.

Operative technique

The surgical procedure consisted of an excision of the colon followed by a close perimuscular dissection of the rectum down to the pelvic floor. The rectum was transected a few centimetres above the anorectal junction and the rectal stump was everted through the anus. This rectal stump was transected at the level of the dentate line and an ileoanal anastomosis was performed manually under direct vision as previously described for coloanal anastomosis[6]. The 18 patients had a J ileal pouch constructed. In each patient, the ileoanal anastomosis was protected by means of a defunctioning ileostomy which was closed 8–12 weeks later.

Clinical test

The frequency of bowel movements was recorded on a diary card for 7 days before the study; no special diet was given.

Anal sphincter studies

Anal manometry (1). Pressure recordings were made with a probe made of three latex balloons tied to polyethylene tubes and connected to pressure transducers[7]. The balloon at the tip of the probe was used to distend the rectum. The second and third balloons (10 mm apart) were filled with water and placed in the upper and lower anal canal respectively. The probe was introduced so that the distal tip of the lowest balloon remained just at the anal margin. From 10 to 100 ml of air was injected into the rectal balloon for 1 min to elicit a rectoanal inhibitory reflex which was recorded in the upper part of the anal canal. Each distension was separated by a 1-min period.

Anal manometry (2). Radial pressures in the anal canal were measured using a rigid probe featuring four perfused channels (internal diameter 0·8 mm) with side-ports 90° apart[8]. A latex balloon was located at the tip of the probe (7 × 1·5 cm) to measure pouch capacity. The four channels were perfused with water (0·5 ml/min) using a low compliance pneumohydraulic system with pressure transmitted to water-filled strain gauges (Gould, Statham P. 23, California, USA)) and permanently recorded on a Beckmann R511 recorder (Sensormedic, Gayny, France).

After the pouch was evacuated the patient adopted the left lateral position. The probe was passed transanally to about 6 cm, just above the puborectalis, and the side-ports were positioned to permit simultaneous recording from the anterior, posterior, right lateral and left lateral quadrants. The probe was withdrawn in 0·5 cm stages every 2 min,

recording the resting pressures within the anal canal at each level as described by Taylor *et al.*[8]. The probe was then reinserted and the procedure repeated, this time asking the patient to squeeze maximally on the probe for 15 s at each position. At the end of this study, the probe was reinserted at the upper part of the high pressure zone. The bag was inflated with 20-ml increments of air at 20-s intervals, and the sensation threshold volume and maximum tolerable volume (MTV) were measured[9]. Results from this study were compared with those obtained from eight healthy volunteers (five men, three women; mean age 32 ± 3 years).

Saline retention test

Assessment of the anal sphincter stressed in a standard manner was accomplished by inserting a polyvinyl probe (outside diameter 7 mm) into the ileal reservoir until its tip was approximately 9 cm from the anal margin. The probe used for this test had two catheters: one to infuse the saline solution[10] through the tip of the probe and another to record intraluminal pressures during the saline test. The latter catheter (internal diameter 1 mm) was perfused with water (0·5 ml/min) and was located 3 cm from the tip of the probe. While subjects sat on a portable commode with a special volumetric collection vessel, 150 mM NaCl was infused at 60 ml/min for 25 min. The saline continence test was interrupted when the first leakage (>10 ml) appeared, when the subject complained of a sustained feeling of nausea or pelvic discomfort, or when 1500 ml had been infused. The MTV and the volume of the first contraction appearing in the ileal pouch were also measured. At the end of the saline continence test the patients were asked to evacuate the pouch contents as completely as possible over a period of 5 min. The evacuated volume of saline was measured and the efficiency of pouch evacuation was represented by the ratio of the evacuated volume divided by the MTV during the saline test.

Statistical analysis

The results were evaluated using the Mann–Whitney *U* test for unpaired data, P values <0.05 were taken to be statistically significant. Correlation of test results to functional results was carried out by linear regression analysis.

Results

Clinical findings

Stool frequencies (mean ± s.e.m.) at home were 5·3 ± 0·4 per 24 h (range 3–9). During the night this frequency varied from 0 to 3·5 per 24 h (mean ± s.e.m., 1·14 ± 0·26). One patient was incontinent. Seventeen patients were continent and able to defaecate spontaneously; three wore a pad, mostly at night. Nine patients had soiling, mostly during the night. Stool weight varied from 79 to 959 g (mean ± s.e.m., 384 ± 53).

Anal manometry (1)

The length of the pressure zone in patients following ileal pouch anastomosis (mean ± s.e.m., 2·95 ± 0·12 cm) was not significantly different from that of the control population (2·9 ± 0·17 cm, $P>0.05$). The resting anal canal pressure in patients (47·5 ± 6·0 cmH$_2$O) was significantly lower than in the control group (102·5 ± 4·0 cmH$_2$O, $P<0.01$). The squeeze pressures were similar between the two groups (patients, 136·3 ± 10·0 cmH$_2$O; controls, 135·6 ± 11·0 cmH$_2$O, $P>0.05$) (*Table 1*).

Anal manometry (2)

The pressures at the upper part of the anal canal were significantly lower (*Table 2*) in the patients than in the controls. However, the pressure at the lower part of the anal canal and the squeeze contractions did not differ between patients and controls.

The rectoanal inhibitory reflex was elicited in all controls when the latex rectal balloon was distended with small amounts of air (mean threshold 12·5 ml, range 10–20). In contrast, the reflex could be elicited in only one patient despite distension of the balloon up to 100 ml of air. Nevertheless, 16 of the 17 patients with an absent rectoanal inhibitory reflex had normal continence.

Function of ileal pouch

The volume at which sensation threshold was reached was significantly higher in the ileoanal anastomosis group (mean ± s.e.m., 60 ± 14·5 ml) than in controls (12·5 ± 1·5 ml, $P<0.05$).

The MTV or pouch capacity as determined by incremental inflation of a latex bag was 270 ± 23 ml in ileoanal pouch patients, which was not significantly different from the MTV of heathy volunteers (245 ± 22 ml).

Saline retention test

Patients were able to retain 1023 ± 68 ml (mean ± s.e.m.) saline administered at a rate of 60 ml/min (*Table 3*). The volume at which the first contraction in the ileal reservoir appeared was 346 ± 96 ml (range 62–1500 ml). The duration of the first contraction appearing in the reservoir varied from 12 to 40 s (mean ± s.e.m., 25 ± 2·9 s) while the amplitude ranged from 17 to 65 cmH$_2$O (36 ± 4·5 cmH$_2$O). The percentage of the infused saline that was evacuated ranged from 29 to 94 per cent (61·0 ± 4·6 per cent).

The patient with nocturnal faecal incontinence was the oldest patient of this study (aged 73 years). Her resting anal pressure (14 cmH$_2$O) and squeeze contraction (75 cmH$_2$O) were low.

There was no correlation between stool frequency and the following parameters: MTV, anal pressures, percentage evacuation of the infused saline, and the volume at which contraction appeared in the ileal reservoir during the saline continence test. There was, however, a correlation between stool frequency and the maximum retained volume of saline during the saline retention test ($P=0.05$). The anal resting pressure did not differ significantly between the patients with and those without soiling. Nevertheless, five out of nine patients with soiling had a low (<30 cmH$_2$O) resting anal pressure, only one of the nine patients without soiling had a low resting pressure.

Discussion

The technique of ileoanal anastomosis for the treatment of ulcerative colitis and familial polyposis is well documented. At

Table 3 *Results of the saline retention test in patients with ileoanal anastomosis*

Maximum retained volume (ml)	1023 ± 68 (614–1500)
Volume leading to first contraction (ml)	346 ± 96 (62–1500)
Percentage evacuated in 5 min	61·0 ± 4·6 (29–94)

Values are mean ± s.e.m., with range in parentheses the present time attention is focused on the type and size of the reservoir and the conservation of a rectal cuff. The conservation of a rectal muscle necessitated a mucosectomy and it has recently been demonstrated[11] that fragments of rectal mucosa can remain between the pouch and the rectal cuff with the potential risk of recurrence of the disease or carcinogenicity.

Our work shows that conservation of a rectal muscular cuff is not essential in order to obtain good functional results; the daily stool frequency is comparable to that reported by Metcalf *et al* [1]. At 12 months, stool frequency was similar (5·3 ± 0 45 during the daytime). By contrast, during the night, stool frequency decreased from 1 14 ± 0·26 to 0·84 ± 0·24, suggesting adaptation of the ileal reservoir Total resection of the rectum with the pouch anastomosis on the dentate line renders mucosectomy unnecessary and permits removal of the entire rectal mucosa.

It has been proposed that conservation of the rectal muscular cuff is necessary to obtain good clinical results and to ensure a postoperative rectoanal inhibitory reflex. Stryker *et al* [12], conserving the cuff, found that a rectoanal inhibitory reflex was present in only 5 per cent of patients This demonstrated that there may be no relationship between the presence of the reflex and conservation of the rectal cuff. The prerequisite for normal continence is the conservation of mucosa located between the dentate line and the anal margin since numerous nerves endings are situated at this level[13] Furthermore, as proposed by Johnston *et al.*[5], it could be important to perform the anastomosis a few millimetres above the dentate line.

Low anal resting pressure was found in our study, and it was due to a decrease at the upper level of the anal sphincter. This decrease has been observed in other studies[5,14,15] where a rectal cuff was preserved and could be attributed to the surgical technique employed. The surgical technique that we adopted combined the total resection of the rectum, the eversion of the rectal stump, and an anastomosis under direct vision. In our patients the decreased anal pressure might be attributable to the dilatation or eversion of the rectal stump during surgery However O'Connell *et al.*[16] recently showed that the anal resting pressure was not significantly different with or without eversion of rectal stump. There was, in our series, no correlation between resting anal pressure, stool frequencies and the occurrence of soiling. However, low anal pressures ($<30\,\mathrm{cmH_2O}$) were more frequent in patients with soiling[16]. It has not been possible to compare anal function before and after ileoanal anastomosis because 14 out of 18 patients were operated on as emergencies.

Recently Johnston *et al.*[5] suggested that the decrease in anal resting pressure was more important when a mucosectomy was performed. In our study, the maximum anal resting pressure ($47{\cdot}5\,\mathrm{cmH_2O}$) was lower than in Johnston's patients with end-to-end anastomosis ($70\,\mathrm{cmH_2O}$) but higher than in patients with mucosal proctectomy with endoanal pull-through anastomosis ($40\,\mathrm{cmH_2O}$). This result suggests that it could be important to preserve a few millimetres of mucosa above the dentate line to avoid minor faecal leakage.

The pressure at the lower level of the anal sphincter and the squeeze contraction were similar in both the patients and controls, suggesting that the striated muscle of the anus was not affected by surgery.

The volume of the ileal pouch is the second major physiological parameter to influence continence and defaecation[17]. The absence of an ileal pouch is associated with poor clinical results. We did not find any correlation between MTV and stool frequency. Other factors should therefore be examined, such as pouch compliance, maximum volume retained during the saline continence test, percentage of evacuation of the reservoir, the volume at which the first contraction appears in the reservoir, and the duration and amplitude of the ileal contractions.

The ability to retain a large volume of saline was associated with better functional results By contrast, there was no relationship between daily stool frequency and MTV, and between MTV and the retained volume of saline. Thus the volume measured during the saline continence test could allow a more precise assessment of the functional volume of the reservoir.

The percentage of evacuation of the pouch is a good measure of the efficiency of defaecation, and our results are comparable with those of O'Connell *et al.*[18] using a different technique Stryker *et al.*[12] suggested that there was a relationship between the time that elapsed between a pouch being empty and the onset of the first ileal contraction and the daily stool frequency. In our study we did not see this relationship, but the conditions under which the saline retention test was performed were not physiological as the infusion rate of NaCl was 60 ml/min.

In conclusion, during ileoanal pouch anastomosis, conservation of a muscular rectal cuff is not necessary to obtain good clinical results. The total resection of the rectum is a particularly useful procedure where mucosectomy is difficult or when the rectum is small.

One hundred patients with rectal adenocarcinoma were examined preoperatively with rectal endosonography (ES) and 50 were also examined with computed tomography (CT). ES predicted mesorectal lymph node involvement with an accuracy of 83 per cent, sensitivity of 88 per cent, specificity of 79 per cent, positive predictive value of 78 per cent and negative predictive value of 89 per cent. CT in comparison had an accuracy of 57 per cent, sensitivity of 25 per cent, specificity of 91 per cent, positive predictive value of 75 per cent and negative predictive value of 53 per cent. No particular histological architectural feature could be identified as responsible for false positive diagnosis though nodal size was significantly larger in the true positive and false positive group when compared with the true negatives ($P<0{\cdot}001$ *and* $P<0{\cdot}01$ *respectively).*

Keywords: Endosonography, rectal cancer, computed tomography

Pararectal lymph node involvement has considerable prognostic significance in rectal cancer giving one indication of survival prospects and the risk of local recurrence. Studies with large groups of patients generally suggest that the presence of lymph node metastases greatly decreases patients' survival[1–9] There is a close relationship between lymphatic spread and the extent of local tumour invasion, tumour histology and vein invasion[8]. Furthermore, as the number of involved nodes increases, a progressive decrease in survival has been noted[9,10]. The incidence of local recurrence is also increased by the presence of involved nodes[11–14], although this may be less important than extensive tumour invasion[15,16]

The most commonly used method of assessing nodal involvement preoperatively is digital examination, and accuracy is related to clinical experience[17]. A more reliable objective method of determining the presence of involved nodes is needed to improve patient selection for conservative methods of treatment including peranal local excision, radiotherapy, cryotherapy or laser therapy. Endosonography (ES) has been shown to be an accurate method of predicting the degree of local invasion in rectal cancer[18–24]. Can it also accurately predict mesorectal nodal involvement, and how does it compare with a more established radiological technique, computed tomography (CT)?

Patients and methods

One hundred patients with a primary rectal adenocarcinoma have been examined preoperatively with rectal ES and 46 of them were also examined using CT to assess the relative merits of the two techniques in predicting nodal involvement. All the ultrasound examinations were performed and reported by one clinician using a Bruel and Kjaer 1846 scanner*, with a rotating hand held endoprobe, and 5·5 MHz (focal length (FL) 1–4 cm) or 7·0 MHz (FL 2–5 cm) transducers The endoprobe was either introduced blindly into the rectum or placed at the level of the lesion through a specially constructed rectoscope After placement in the lumen a latex balloon, which covers the transducer, was inflated with water for good ultrasonic contact

Ultrasonic prediction of involvement was based on the identification of circular or oval echo-poor lesions in the mesorectum as suggested by Tio and Tytgat[25] in their studies using upper gastrointestinal ES for the examination of oesophageal and gastric malignancies Failure to identify any such area was taken as a negative result At the same time a note was made of the differing echo patterns produced by suspicious extrarectal lesions to see whether, in retrospect, inflammatory or normal nodes could be distinguished from involved nodes just on the basis of the echo pattern.

After resection the specimens were prepared and transverse sections taken for comparison with the radiological images A detailed examination of all the mesorectal lymph nodes within 1 cm of the tumour was made and the histological architecture noted The total number and size of nodes identified, the number of involved nodes and the number of nodes showing 'reactive' changes (defined as the presence of sinusoidal or follicular dilatation, or follicular hyperplasia, or combinations thereof) were included

ES predictions of nodal involvement were compared with histopathological assessments and results analysed using a Spearman rank correlation test[26] Pathological results relating to nodal size were analysed using the Kruskal–Wallis one-way analysis of variance and the Mann–Whitney *U* test[27].

Results

Of the 100 patients studied 56 were men and 44 women and they had an age range of 36–91 years (median 67·5) Subsequently 93 were treated by either anterior resection or abdominoperineal excision. Seven patients were treated by peranal local excision and in two cases, local lymph nodes adjacent to the tumour were also excised, the patients having refused a major resection.

Endosonography

During the initial phases of this study it soon became apparent that normal nodes and most 'reactive' nodes were not imaged and that the presence of an echo-poor lesion in the pararectal tissues was usually indicative of a lymph node metastasis (*Figure 1a* and *b*) ES could not, however, differentiate between involved nodes and islands of tumour outside the wall. The smallest positive node detected had a diameter of 0·3 cm. No hyperechoic nodes were imaged. Some echo-poor nodes detected by ES did not contain any tumour when isolated and examined pathologically (*Figure 2*).

ES predicted lymph node involvement in 49 cases and lack of involvement in 46 cases. Comparison with histopathology showed that there were 38 correct positives, 41 correct negatives, 11 false positives and 5 false negatives. Correlation of ES predictions and histopathology gave a correlation coefficient of 0·67 (d.f =93, $P<0{\cdot}001$) (Spearman rank correlation)

The accuracy of prediction of lymph node involvement was 83 per cent. The sensitivity for predicting involvement was 88 per cent, specificity 79 per cent, positive predictive value 78 per cent and negative predictive value 89 per cent.

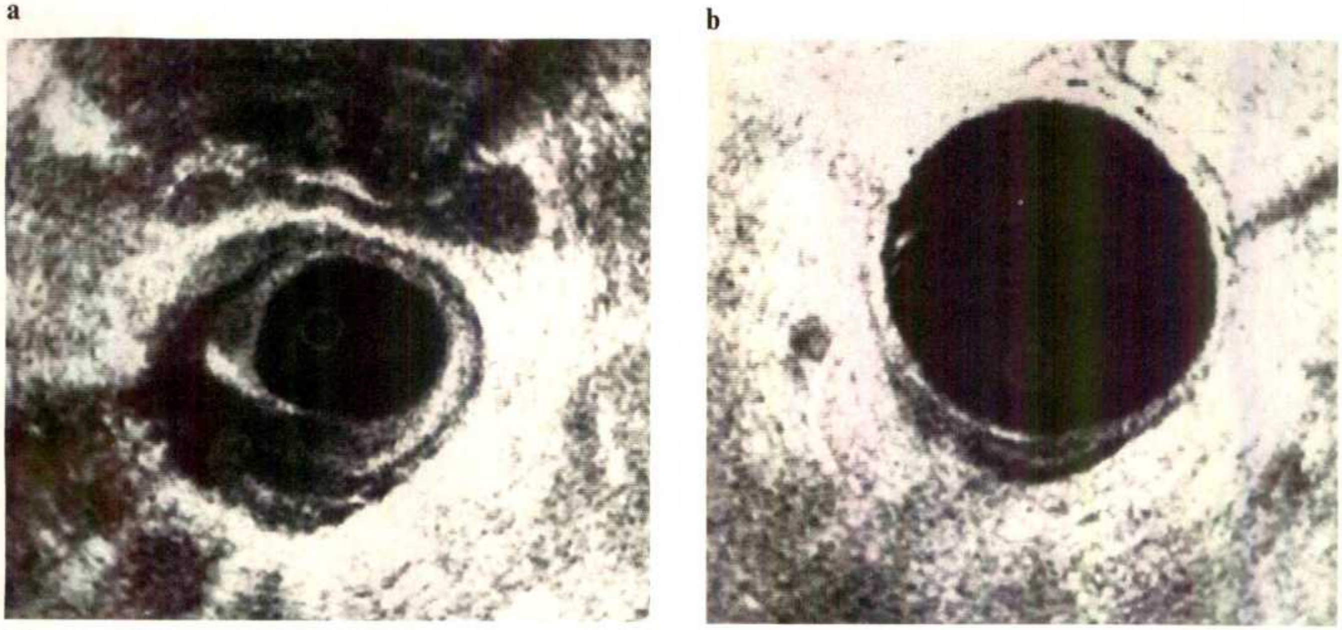

Figure 1 **a** *This ultrasound scan shows a transmural tumour (uT3) which, at this level, does not appear to have any nodal metastases;* **b** *at the upper limit of the same tumour a small echo-poor nodal metastasis was imaged in the 9 o'clock position*

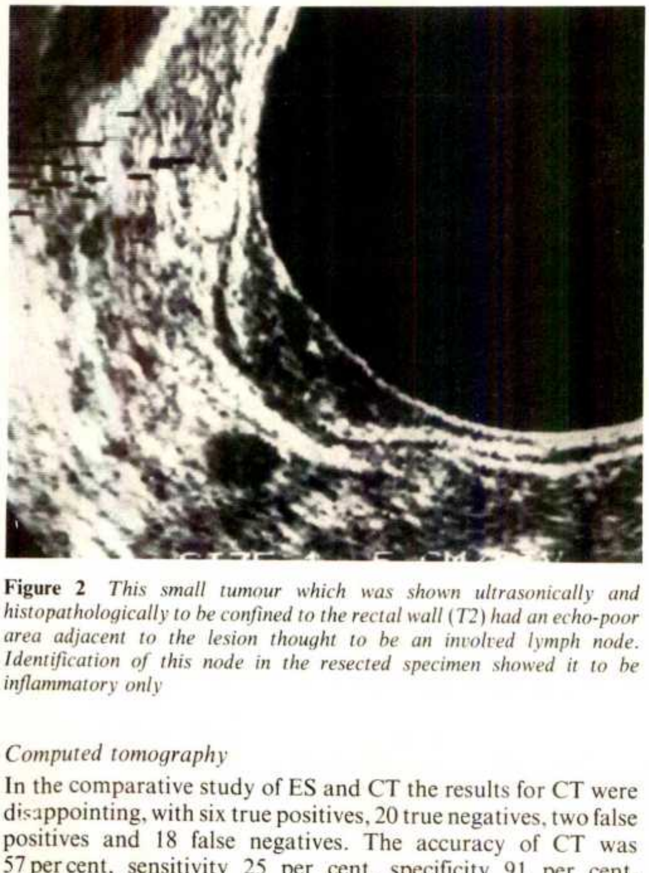

Figure 2 *This small tumour which was shown ultrasonically and histopathologically to be confined to the rectal wall (T2) had an echo-poor area adjacent to the lesion thought to be an involved lymph node. Identification of this node in the resected specimen showed it to be inflammatory only*

Computed tomography

In the comparative study of ES and CT the results for CT were disappointing, with six true positives, 20 true negatives, two false positives and 18 false negatives. The accuracy of CT was 57 per cent, sensitivity 25 per cent, specificity 91 per cent, positive predictive value 75 per cent and negative predictive value 53 per cent. The comparative results are presented in *Table 1*.

It would seem that CT can only identify large nodes (*Figure 3*) in this series identified only those larger than 1·5 cm in diameter. This ability alone is not sufficient to differentiate inflammatory from malignant nodes.

Histopathology

In 56 patients a detailed examination was performed to determine if any one histological feature or combination of features was responsible for the endosonographically false positive diagnoses. This group was chosen solely on the basis that a complete longitudinal assessment of the tumour had been made and also that there was detailed histopathological information about all nodes within 1 cm of the tumour. The results from these cases showed that there were 24 true positives, 24 true negatives, seven false positives and one false negative. All nodes were

ES	87	92	82	85	90

CT, computed tomography; ES, endosonography; PPV, positive predictive value; NPV, negative predictive value

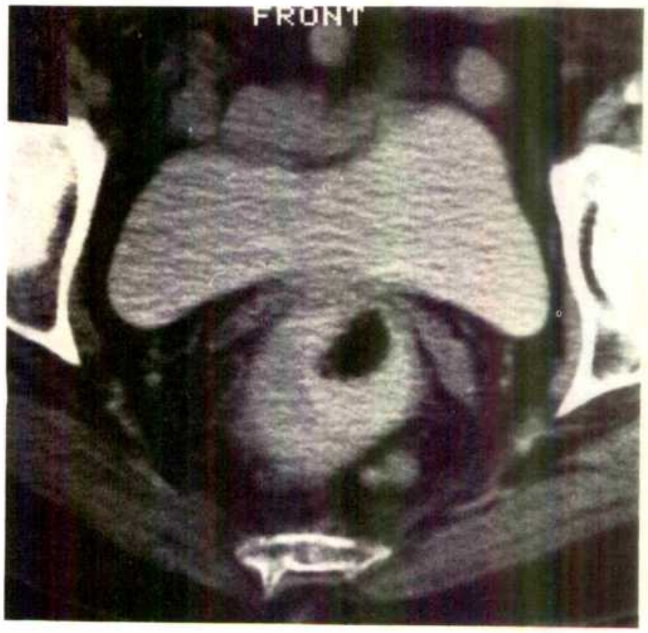

Figure 3 *This computed tomography scan demonstrates a rectal tumour with a large adjacent involved lymph node*

Table 2 *A comparison of histopathological nodal size in the endosonographically true negative, true positive and false positive groups*

Endosonographic status	Histological status	Size range (cm)	Median (cm)
Negative	Negative nodes	0·05–1·2	0·4
Positive	Positive nodes Negative nodes	0·2–1·3 0·1–0·7	0·7 0·38
Positive	Negative nodes	0·2–0·8	0·5

examined histologically for the presence of tumour metastases or the presence of 'reactive changes' as shown by the presence of sinusoidal dilatation, follicular hyperplasia, sinusoidal hyperplasia or combinations of these characteristics.

This pathological examination failed to show that any particular histological architectural feature or combination of features was responsible for the misdiagnosis of nodal involvement.

Nodal size

The histopathological size of nodes within 1 cm of the tumour was also measured in the endosonographically true positive, true negative and false positive groups to determine whether any overall difference in size existed in the lymph nodes detected in the three groups. In this analysis there were nodes from 51 resections and of these ES assessment gave 25 true negatives, 20 true positives, five false positives and one false negative. The sizes of nodes in the individual groups varied considerably (*Table 2*).

These data have been compared using the Kruskal–Wallis test for independent variables ($H = 34·96$) and subsequently using the Mann–Whitney U test. Comparison of the sizes of the histologically involved and non-involved nodes in the endosonographically 'true positive' group showed a statistically significant difference ($U = 370$, $P < 0·001$). On comparison of the histologically involved nodes in the endosonographically true positive group with the histologically negative nodes in the endosonographically false positive group no significant difference was found ($U = 264$, $P = 0·098$). In addition there was a significant difference in size between the histologically involved nodes in the endosonographically true positive group and those in the endosonographically true negative group ($U = 878$, $P < 0·001$). There was also a significant difference in histological size of nodes between the endosonographically false positive and the true negatives ($U = 350$, $P < 0·01$) (*Table 2*).

Discussion

Various methods have been used to evaluate the status of mesorectal lymph nodes before treatment. At present digital examination is the most commonly used method but it is not very accurate[17]. Nicholls *et al.*[17] found in their study that 57–67 per cent of patients thought clinically not to have involved nodes were found by the pathologist to be node negative while about two-thirds thought to have involvement by the clinician had this status confirmed by the pathologist. The registrars correctly identified two of 25 cases (8 per cent) with lymphatic metastases while two specialist clinicians correctly identified node positive patients in 12 of 24 (50 per cent) and 15 of 27 (55 per cent) cases respectively.

Other radiological techniques have been used to try to predict nodal involvement. These include iliopelvic lymphoscintigraphy[28,29], monoclonal immunoscintigraphy[30–32], CT[24,33–37] and more recently nuclear magnetic resonance[38,39]. Thus far, simple lymphoscintigraphy has been disappointing and the position of immunolymphoscintigraphy is yet to be fully established[28–32].

CT studies suggest that only nodes of ⩾1 cm can be identified[24,33–37]. Node size is, of course, no indication of involvement with tumour and may just represent reactive changes. Nuclear magnetic resonance has been shown to be as specific but less sensitive than CT in the prediction of nodal involvement[38]. However, it is a new technique and further experience is needed for a more complete evaluation of its role.

Table 3 *The accuracy of endosonography in predicting mesorectal nodal involvement*

	No. of patients	No. correct	Accuracy (%)
Hildebrandt *et al.*[22]	27	20	74
Rifkin and Wechsler[24]	81	70	86
Saitoh *et al.*[21]	71	52	73
Beynon *et al.* (current data)	95	79	83

Three reports on the effectiveness of ES in the detection of mesorectal nodes have appeared in the literature[21,22,24]. Saitoh *et al.*[21] reported an accuracy of 73·2 per cent for the node positive group and 82·3 per cent for the node negative group (19 false positives and three false negatives), although they noted that metastatic and non-metastatic nodes as small as 5 mm could be detected. Hildebrandt *et al.*[22] found that since using a 7 MHz transducer lymph node metastases have been identified. In the 27 patients scanned preoperatively, 12 were thought to have metastatic involvement of pararectal lymph nodes. However, after resection this was confirmed in only six cases while the other six showed reactive changes. One of the histologically involved nodes was not detected endosonigraphically. Rifkin and Weschler[24] identified ten of 15 patients with positive nodes with six false positives in the remaining 66 patients. This gave an overall sensitivity of 67 per cent, specificity of 91 per cent, positive predictive value of 63 per cent and negative predictive value of 92 per cent.

Our results compare well with these reports (*Table 3*). It appears that involved mesorectal nodes can be imaged, although there is a problem with false positive diagnoses. Despite this, in our hands, the level of accuracy is higher than can be offered by CT, and is higher than the reported accuracy of digital examination[17] or nuclear magnetic resonance imaging[38].

The false positive diagnoses of nodal involvement cannot be explained by the architecture of the nodes in the mesorectum but may possibly be explained by a difference in the size of mesorectal nodes. Large reactive nodes often have the endosonographic appearance of involved nodes. In addition blood vessels in cross-section have a similar appearance to nodes and could only be distinguished from them by their tubular or branching appearance when the probe was moved up and down the rectum. Fine needle aspiration, guided by ultrasound, would be one way of determining the true status of a node at ES.

In our experience ES has already influenced management decisions, identifying those patients both suitable and unsuitable for peranal local excision. It may well be that the management of middle- and lower-third tumours of the rectum, which are suitable for restorative low anterior resection, could be influenced by accurate preoperative information about nodal status.

Acknowledgements

We are grateful to the surgeons of the Bristol Royal Infirmary, Southmead, Frenchay and Weston General Hospitals for permission to study their patients. Support for this work was provided by the Cancer Research Campaign.

Value of a risk questionnaire in screening for colorectal neoplasm

The value of a postal questionnaire and of Hemoccult II (Smith Klein Diagnostic Inc., Sunnyvale, California, USA) testing in screening for colorectal neoplasms was compared. In the questionnaire, the subjects were asked about previous treatment for colorectal neoplasm and rectal bleeding during the previous 6 months, specified as to type. All participants were asked to perform Hemoccult II blood testing over 3 days. Of 13 759 randomly selected subjects 9040 (66 per cent) performed the test and returned the questionnaire. Three hundred and fifty-four subjects with a positive Hemoccult II test and/or a proven previous colorectal neoplasm had a full assessment including double-contrast enema and rectosigmoidoscopy to 60 cm. Eighteen carcinomas and 61 adenomas were thus diagnosed. The population was followed for from 20 to 29 months, during which time rescreening was undertaken. An additional 34 subjects with carcinomas and 90 with adenomas were identified during this period. A significant correlation between the presence of a colorectal neoplasm and a previous history of colorectal neoplasm, a positive Hemoccult II and a previous history of bright red bleeding but not dark bleeding was found. The possibility of diagnosing a neoplasm was two, four and 19 times higher in a subject with a previous history of bleeding, a history of colorectal neoplasm,or a positive Hemoccult II respectively. Screening by faecal occult blood testing, therefore, at the moment seems to bethe best and only practicable method.

Keywords: Faecal occult blood, testing, screening, colorectal carcinoma

Department of Surgery, Sahlgrenska Sjukhuset, S-413 45 Goteborg, Sweden

Correspondence to
Dr J. Kewenter

The risk of developing colorectal cancer is increased in some diseases but it is also closely related to age. Thus, the incidence of colorectal cancer in Swedish subjects between 45 and 49 years of age is 15 per 100 000, compared with 131 per 100 000 between 65 and 69 years of age[1] The possibility of curing colorectal cancer with surgery is good if the carcinomas are diagnosed at an early stage. General screening of subjects in higher age groups for this type of cancer has therefore been advocated[2]. The most frequently used method is screening by faecal occult blood testing but risk questionnaires have also been advocated as a useful screening tool[3]. These questionnaires have usually included questions about abdominal symptoms, bleeding, previous colorectal neoplasms and a family history of colorectal neoplasms.

One aim of this study was to determine the value of a questionnaire as a screening tool for early detection of colorectal cancer. The other aim was to determine whether subjects with a history of colorectal neoplasms and/or colorectal bleeding and/or positive Hemoccult II (Smith Klein Diagnostic Incorporated, Sunnyvale, California, USA) constitute special risk groups This investigation was part of a larger screening study for the early detection of colorectal neoplasms with the aid of faecal occult blood testing[4].

Patients and methods

All 27 700 inhabitants of the City of Gothenburg born between 1918 and 1922 (60–64 years of age in 1982) were randomly allocated to a control or a test group. The control group consisted of 13 744 and the test group of 13 759 individuals.

Three Hemoccult II tests, a letter of instruction, a questionnaire and a prepaid reply envelope were mailed out to the subjects in the test group The subjects were asked to perform Hemoccult II occult blood testing with two samples from each of three consecutive stools and mail the slides back to the hospital immediately after the last test occasion Two reminder letters were sent out to subjects who did not answer The last letter included another set of Hemoccult II slides

The test group was divided into two subgroups and slides from older subjects were not hydrated before development while slides from younger subjects were rehydrated The latter persons were asked to maintain a low fruit and vegetable intake for 2 days before sample collection The subjects in both groups were also asked to avoid food made of blood and to avoid vitamin C tablets This was performed in order to study the sensitivity of the test

In the questionnaire, the subjects were asked if they had previously been treated for a colorectal neoplasm and if they had noticed blood from the anus during the 6 months before testing The subjects with bleeding were asked whether the bleeding had been dark or bright red The case notes of those who stated that they had previously been treated for a colorectal neoplasm were collected.

Individuals with one or more positive Hemoccult II tests and/or a previous history of colorectal neoplasm were called to the hospital for assessment This included a digital rectal examination, proctoscopy and rectosigmoidoscopy with a flexible instrument 60 cm long All subjects were then referred for double-contrast enema examination of the colon. Rescreening was offered to all subjects in the test group from 16 to 22 months (mean 20 months) after the first study All slides were rehydrated at the time of rescreening Subjects with negative Hemoccult II test and without a history of neoplasm were not examined.

Follow-up of all subjects was achieved by continuous quarterly contact with the Cancer and Death Registry, weekly contact with the three departments of surgery in the City of Gothenburg and continuous contact with the register at the Department of Pathology. Through these registers it was also possible to follow up the few subjects who moved to other localities in Sweden It should be pointed out that the Swedish health care system covers the vast majority of all hospital care In this system the patient is normally treated in his local hospital and only at other hospitals if referred. By these routines, it was judged virtually impossible for a person in our studied groups with a diagnosed colorectal neoplasm to be lost to follow-up The average follow-up of patients was 24 months (20–29 months), including the rescreening period.

All excised neoplasms were examined by the same pathologist

New batches of Hemoccult II were evaluated at the Reference Laboratory for Fecal Occult Blood Testing, Memorial Sloan Kettering Cancer Centre, New York City, USA.

Statistical methods

The correlation between each of four variables and the presence of neoplasm was tested with Fisher's exact test. The same test was also used for testing the correlations between the four variables. In order to test the correlation between a variable and presence of neoplasm, eliminating the influence of another variable, Mantel's test was used[5]. Finally, the probability of neoplasm was estimated as a function of the variables significantly correlated to presence of neoplasm by applying a logistic model[6]. All tests were two-tailed.

The probability of neoplasm was estimated as a function of A (0 if no previous colorectal neoplasm, 1 otherwise), BC (0 if no blood or dark blood, 1 if bright red blood) or D (0 if Hemoccult II negative, 1 otherwise) by assuming that the probability is $(1+\mathrm{Exp}(-C_1A-C_2BC-C_3D-C_4))^{-1}$, were C_1, C_2, C_3 and C_4 are constants.

For any combination of the values of the variables A, BC and D, the probability of neoplasm can be calculated by means of the model and the estimated constants. There are eight combinations. The constants obtained were used to calculate the level of risk for the different factors.

Results

Of the 13 759 subjects in the test group 9040 returned the slides and the questionnaire (66 per cent) and 1687 more returned the questionnaire only. This study refers only to those who returned both Hemoccult II and the questionnaire. Of these 9040 subjects 1164 (12·9 per cent) had noticed blood from the anus at least once during a 6-month period before the testing. Of these, 22 had been treated for a colorectal neoplasm. Another 50 subjects had previously been treated for colorectal neoplasm but had no history of rectal bleeding (*Table 1*). Eighty-eight subjects who had noticed blood (7·6 per cent) had a positive Hemoccult II test. Three of the subjects with a history of a colorectal neoplasm but without a history of rectal bleeding also had a positive Hemoccult II test. The result of the complete assessment (304) among those with a positive (Hemoccult II) test (349) is shown in *Table 1*. It can be seen from *Table 1* that all subjects with diagnosed neoplasm and a history of bleeding had noticed bright blood. None had noticed dark blood.

The results of the assessment and follow-up during 24 months of subjects with a positive questionnaire are shown in *Table 2*. In 818 subjects with bright bleeding the positive predictive value for neoplasm was six times higher than among the 346 subjects who had noticed dark bleeding.

Of the subjects with a positive Hemoccult II, 91 had a positive history (bleeding and/or previous colorectal neoplasm) while 258 subjects with a positive Hemoccult II had neither noticed any bleeding nor had any history of colorectal neoplasm (*Table 3*). The number of diagnosed neoplasms at the first and second screening and in the interval between the two screening occasions (24 months) is shown in *Table 3*. The number of subjects in the group with a negative Hemoccult II test but with a positive history during the same period is also shown in the table. The positive predictive value was twice as high among the subjects with a positive Hemoccult II test and a positive history compared with those who had a positive Hemoccult II test but a negative history, and 19 times higher than for those with a negative Hemoccult II and a positive history (*Table 3*).

In the questionnaire, 149 subjects stated that they had previously been treated for a colorectal neoplasm. When the hospital records were studied only 72 had in fact been treated for a colorectal neoplasm. Of these, 21 had previously been operated on for colorectal cancer, 22 for tubular adenomas and nine for tubovillous adenomas. The microscopic report could not be found in the remaining 20 subjects with benign adenomas. Thus, a misconception about the diagnosis among the 149 subjects occurred in no less than half of them (72 of 149 subjects). Anal polyps, haemorrhoids and hyperplastic noduli were the main reasons for the misconceptions. Of the 72 subjects with a proven history of previous colorectal neoplasm, 22 had noticed blood from the anus during the last 6 months (*Table 1*).

All 72 subjects with a previous history of colorectal neoplasm were later called separately for a reassessment. Four of these subjects, however, had died by the time of follow-up, nine subjects did not want to participate and another three could not be located. Thus, 56 of the 72 subjects participated in the review. Five adenomas were diagnosed among these 56 subjects at the initial screening and two more during the follow-up. Two of these adenomas were found among the subjects with a positive Hemoccult II test.

The calculations for demonstrating possible correlations between the presence of neoplasms and the different variables are based on the figures in *Table 4* and the results of these calculations are shown in *Tables 5, 6* and *7*.

It will be seen from *Table 5* that there is an increased possibility of finding a neoplasm in a subject who has a history of colorectal neoplasm, a history of bleeding or a positive Hemoccult II. There was a significant correlation with the presence of a neoplasm if the bleeding was bright but not if the bleeding was dark. However, it cannot be excluded that these correlations were due to one or more of the factors which were alone strong enough to be responsible for the different results. Each variable was therefore tested in such a way that the influence of other variables was eliminated. This was done after the correlations between the variables had been tested (*Table 6*). All variables were significantly correlated except a history of colorectal neoplasm and the result of Hemoccult II testing. There was a positive correlation between the presence of a colorectal neoplasm and a history of colorectal neoplasm, a positive

A	0·002
B	<0·001
*BC*1	<0·001
C	<0·001
*BC*2	0·195
D	<0·001

A, previous colorectal neoplasm (no = 0, yes = 1), *B*, colorectal bleeding (no = 0, yes = 1); *C*, bright blood (= 1) or dark blood (= 2), *D*, Hemoccult II (negative = 0, positive = 1), *BC*1 (0 if *B* = 0, 1 if *C* = 1), bright bleeding, *BC*2 (0 if *B* = 0, 1 if *C* = 2), dark bleeding There is an increased chance of finding a neoplasm in subjects who have a history of colorectal neoplasm, a history of bleeding or a positive Hemoccult II test There was a significant correlation if the bleeding was bright but not if the bleeding was dark

Hemoccult II and bright red bleeding, but not dark bleeding (*Table 7*)

The probability of colorectal neoplasm was estimated as a function of these variables by means of a logistic model (see statistical methods). The estimation of the constants gave the following result. C_1 1·28, C_2 0·72, C_3 2·93, C_4 −4·35. It was found that the possibility of diagnosing a colorectal neoplasm was four times higher in subjects with a history of colorectal neoplasm than in subjects without such a history, twice as high if the subjects had a history of colorectal bleeding and 19 times higher if they had a positive Hemoccult II as opposed to a negative Hemoccult II test.

Details concerning the incidence of neoplasia in the test and control groups, the distribution of the carcinomas according to Dukes' classification, the number of neoplasms found at re-screening, the site and size of the lesions and the sensitivity and specificity in the different groups have recently been published[4,7,8].

Discussion

The most commonly used screening method for colorectal cancer is the guaiac-based test for faecal occult blood. In order to increase the pick-up rate of neoplasms, Hemoccult II testing has in some studies been combined with a risk questionnaire[3] However, questionnaires which are directed towards symptoms seem to be very difficult to construct as symptoms similar to those of colorectal cancer are very common in the community and non-specific in character. Questions concerning clinical symptoms were therefore not included in the present questionnaire.

Macroscopical rectal bleeding is a relatively common symptom in subjects with colorectal neoplasms and a question about it was therefore included. Theoretically, it might be more accurate to investigate those patients with a history of bleeding during a 6-month period before the study instead of investigating those with a positive Hemoccult II test. However, no less than 12·9 per cent of all subjects (1164 of 9040) who answered the questionnaire had noticed blood once or more during a 6-month period before answering the questionnaire. This high percentage makes it practically impossible to investigate everyone with such a history. A similar, high figure was found in one UK study but in another UK study only 6·6 per cent of 527 subjects had noticed bleeding from the back passage during the corresponding time period[9,10]. This difference in incidence of rectal bleeding might be due to a difference in the ages of the two populations. If the group of 1164 subjects with a history of bleeding had alone been assessed only 11 of the 52 colorectal carcinomas and only 25 per cent of the adenomas would have been diagnosed Thus, the vast majority of subjects with colorectal neoplasm in a screened population had not noticed any bleeding. However, as could be expected, the number of neoplasms diagnosed among those with a history of bleeding was significantly higher than in those without such a history and there was a significant correlation between the presence of a neoplasm and colorectal bleeding.

The type of rectal bleeding, dark or bright, has been considered to be predictive of the presence of a colorectal neoplasm[11]. In subjects with neoplasms dark bleeding is considered to be significantly more likely than bright bleeding[11]. However, in our study group, in contrast, a significant correlation was found between the presence of a neoplasm and a history of bright bleeding but not between the presence of a neoplasm and dark bleeding The explanation could be that 'dark

Table 6 *Test of correlation between the different variables*

Test of correlations between variables	Two-tailed *P*-value obtained by Fisher's exact test

B and *C*	<0·001
C and *D*	0·001

A, previous colorectal neoplasm (no = 0, yes = 1), *B*, colorectal bleeding (no = 0, yes = 1), *C*, bright blood (= 1) or dark blood (= 2), *D*, Hemoccult II (negative = 0, positive = 1) All variables were significantly correlated except a history of previous colorectal neoplasm and the result of Hemoccult II testing

Table 7 *Test of correlation between the different variables and the presence of a neoplasm when the influence of other variables had been eliminated*

Test of correlation between presence of neoplasm and variable	Eliminating the influence of variable	Two-tailed Mantel's test (*P* value)
A	*B* and *C*	0·012
B	*A*	<0·001
C	*A*	<0·001
B	*D*	<0·009
C	*D*	0·004
D	*B* and *C*	<0·001

A, previous colorectal neoplasm (no = 0, yes = 1), *B*, colorectal bleeding (no = 0, yes = 1), *C*, bright blood (= 1) or dark blood (= 2); *D*, Hemoccult II (negative = 0, positive = 1) bleeding' was synonymous with dark faeces in some cases where the 'dark' faeces were not due to blood. It is possible that a higher correlation with bleeding and colorectal neoplasm would have been achieved using a more detailed questionnaire. However, the difficulty in predicting the presence of colorectal neoplasms from the type of rectal bleeding has been clearly shown[11].

Patients who have had a colorectal neoplasm are considered to have an increased risk of developing a new colorectal neoplasm[12]. It therefore seemed logical to include a question about the presence of previous colorectal neoplasms in the questionnaire. One hundred and forty-nine subjects answered that they had previously been treated for a colorectal neoplasm. We checked this information with the department where these subjects had been treated. It was then found that the diagnosis was correct in only half of the subjects (72 out of 149). Thus, half of the subjects were unfortunately unaware of the reason for their previous treatment. We conclude that it is necessary to confirm objectively the case history concerning previous neoplasms before the subject is called for a check-up based upon information obtained in a questionnaire. There is a significantly increased chance of diagnosing a new colorectal neoplasm if the subject has a proven history of colorectal neoplasm. The risk was estimated to be four times higher than in those without such a history.

The use of a questionnaire entails a lot of work. The work involved in checking the information about previous treatment for colorectal neoplasms and the very high number of subjects in these age groups with a history of bleeding makes a questionnaire unsuitable as a screening tool, considering its low specificity and sensitivity. It is possible that reformulation of the questions and other types of questions would have yielded more pertinent information. The chance of diagnosing a colorectal neoplasm was four times higher in a subject with a previous history of colorectal neoplasm than in one with no such history and twice as high in subjects with a history of bleeding than with no history of bleeding, but the chance of diagnosing a neoplasm was 19 times more likely if the Hemoccult II test was positive than if it was negative Screening for early detection of colorectal neoplasms by faecal occult blood testing therefore seems to be the best and only practicable method.

From 1978 to 1985, 297 patients were entered in a double-blind randomized trial comparing levamisole to placebo as adjuvant therapy of Dukes' C carcinoma of the colon. Therapy consisted of from two to five tablets of 50 mg levamisole (or placebo) twice a week, depending on bodyweight for 1 year. Levamisole was generally well tolerated, with only four reversible cases of agranulocytosis reported among 129 patients. The trial failed to show a benefit of levamisole on disease-free survival ($P = 0{\cdot}53$) *or on survival* ($P = 0{\cdot}35$). *There was no difference between the two treatment groups in terms of number of disease relapses, sites of relapse, or time to relapse. The proportion of patients still alive at 5 years was 51 per cent (standard error, 5·5 per cent) in the levamisole group* versus *39 per cent (standard error, 5·4 per cent) in the placebo group.*

Keywords: Randomized clinical trial, double-blind treatment, colon neoplasm, immunotherapy

Colon carcinoma is second only to lung cancer as a cause of cancer-related deaths in the USA and western Europe[1] Despite intensive investigation, the results of treatment for colon cancer remain poor and have changed little in the last three decades. Surgical treatment is the primary management of colorectal tumour with roughly 80 per cent of the patients being operable at the time of diagnosis[2,3]. Even when resection is considered curative, the overall 5-year survival is only 50 per cent[4,5].

The prognosis of patients with colon cancer is clearly related to the extent of tumour spread at the time of diagnosis, as assessed by the classification of Dukes[6] or its later modifications[7]. The proportion of patients alive 5 years after surgery is of the order of 80 per cent for tumours confined to the submucosa (Dukes' A), 60 per cent for tumours penetrating deeper into the bowel wall (Dukes' B_1), 45 per cent for tumours extending through the serosa into the pericolic fat (Dukes' B_2), and as little as 25 per cent if there is regional lymph node involvement (Dukes' C)[8–10]. Thus patients with regional lymph node involvement must be considered as potentially having occult disseminated disease even when their primary tumour has been resected for cure and are therefore ideal candidates for adjuvant therapy.

At the time this trial was started (1978), the benefit of adjuvant chemotherapy in colorectal cancer was unclear, and the question has remained controversial[2,11–14]. Promising results had been published on the use of immunotherapy both in the advanced disease and in the adjuvant setting. The main agents investigated were Bacillus Calmette-Guérin (BCG), methanol extracted residue of BCG (MER), *Corynebacterium parvum* and levamisole. BCG had been used in advanced intestinal cancer[15] and as adjuvant to surgery in colon cancer patients with lymphatic extension[16,17]. MER had been used in advanced colorectal cancer patients[18]. *C parvum* had been used in association with chemotherapy in bronchial and advanced breast carcinomas[19]. However, none of these trials was controlled and the interpretation of their results was disputed.

Levamisole is a pure chemical which was first used as an anthelmintic drug. Its effect on the immune response was found by Renoux and Renoux[20] who reported that levamisole enhanced immunization of mice against *Brucella abortus*. Since this first observation, levamisole has been considered to be a modifier of the immune response. Various reports[21] have suggested that levamisole could have an enhancing effect on the functions of B lymphocytes, T lymphocytes or macrophages Levamisole has also been considered to be an antianergic agent, restoring normal immune response in immunosuppressed situations. A restoration of delayed hypersensitivity reactions in cancer patients following levamisole therapy was reported by several investigators[22,23]. Two controlled studies using levamisole had been published before the beginning of our trial, one in patients with resectable bronchial carcinomas[24,25] and one in patients with advanced breast carcinomas[26]. Both of these trials used a fixed dose of 150 mg per day on 3 consecutive days every other week. In the first of these trials, a significant reduction was observed in the number of relapses in patients weighing <70 kg. In the second trial, levamisole was combined with radiotherapy, and led to an apparent reduction in the number of relapses and deaths compared with those of a control group Non-randomized trials of levamisole in the treatment of colorectal cancer[27] and of gastric cancer[28] following tumour resection had suggested a possible improvement in survival, but information from properly randomized trials was lacking.

This prompted the European Organization for Research and Treatment of Cancer (EORTC) Gastrointestinal Tract Cancer Cooperative Group to initiate a double-blind randomized clinical trial comparing levamisole to placebo in patients after 'curative' resection of Dukes' C colon cancer.

Patients and methods

Eligibility criteria

Patients were eligible for this trial if they fulfilled all of the following criteria histological confirmation of the presence of primary adenocarcinoma of the colon sited between the caecum and the sacral promontory, curative surgical intervention, without any macroscopic or histological residual tumour tissue, local or metastatic, observed during or after the operation, histologically confirmed involvement of one or more lymph nodes, i.e. Dukes' C classification of the excised tumour The patients were required to have completely recovered from the acute effects of surgery, to have no evidence of infection and to have adequate haematological indexes (white cell count >2000 per mm^3, platelet count $>150\,000$ per mm^3) and adequate renal function (creatinine clearance $>60\ ml\ min^{-1}$) There was no age limit. Patients were excluded in the following cases presence of another cancer, other than basal cell carcinoma of the skin; major mental disturbance, previous history of agranulocytosis or known allergy to drugs, history of ulcerative or granulomatous colitis, or familial polyposis, previous radiotherapy, chemotherapy, or immunotherapy

Surgery

The surgical excision had to include a removal of the lymphatic drainage by a complete resection of the mesentery of the cancer-bearing segment. The surgeon had to confirm the absence of any cancerous tissue in the peritoneum, the liver and other organs of the abdominal cavity.

Randomization method

Eligible patients were entered on trial immediately after the histological confirmation of a Dukes' C lesion, as soon as possible after surgery. Numbered boxes containing tablets of either placebo or levamisole had been provided to all investigators and were used in sequential order. The EORTC Data Center was informed of a patient's entry into the trial by a telephone call. Placebo or levamisole had been assigned to the successive box numbers at random, using a permuted block design. The boxes and tablets of levamisole were indistinguishable from their placebo counterparts, so that neither the attending physician nor the patient was aware of the actual treatment received.

Placebo or levamisole administration

Tablets containing 50 mg levamisole (or placebo) were taken on the same two consecutive days of each week for a period of 1 year or until evidence of relapse or severe toxic symptoms. The daily dosage of levamisole (or placebo) was adapted to body weight throughout the therapy period: 100 mg daily (i.e. two tablets) for patients weighing <50 kg, 150 mg for those weighing 51–70 kg, 200 mg for those weighing 71–90 kg, and 250 mg for those >90 kg.

Follow-up examinations and criterion of relapse

Standard clinical examinations (including the pelvis and the liver), chest X-rays, and complete blood counts were required before entry into the trial, every month during the first 3 months of adjuvant therapy, and every 3 months during the remaining period. Liver scan, intradermal tuberculin reaction or other immunological tests, rectoscopy, double-contrast barium enema and carcinoembryonic antigen (CEA) measurement were optional at the discretion of the attending physician.

Relapse was defined as any morphological proof of the appearance of tumour by palpation, X-ray, scintigraphy, laparoscopy, colonoscopy or laparotomy. An elevation of CEA level prompted the search for tumour recurrence but was not considered alone as evidence of relapse.

Statistical methods

Survival was measured from the date of surgery for the primary tumour to the date of death from any cause. Disease-free survival was measured from the date of surgery to either relapse or death, whichever occurred first. Survival and disease-free survival curves were estimated by the product-limit procedure of Kaplan and Meier[29], and compared using the log rank test[30]. Comparisons were retrospectively adjusted for prognostic factors using a stratified log rank test. All statistical tests were two-tailed.

Results

Patient cohort

Two hundred and ninety-seven patients were entered into the trial by 19 institutions between April 1978 and December 1985. Institutional problems were encountered in two institutions after entry of five and three patients respectively; these institutions were excluded from the trial and no data could be obtained on their eight patients (placebo, five, levamisole, three). The number of patients available for analysis was thus 289. Seven patients were found to be ineligible after entry to the trial because they had metastatic disease; one patient was found to be ineligible because he had no regional lymph node involvement. These eight ineligible patients (placebo, two; levamisole, six) were included in all analyses to avoid any statistical biases[31]; excluding them from the analyses did not materially affect the results. Adjuvant therapy was never started in eight patients (placebo, two; levamisole, six). These patients were included in all but the toxicity analyses.

At the time of this analysis, the mean follow-up time for surviving patients was 3 years.

Patient characteristics

Table 1 shows the main prognostic features of the patients. The only noteworthy difference between the two treatment groups was the significantly larger number of patients with four or more positive lymph nodes in the placebo group. Detailed data on the tumour histopathology were collected and their prognostic importance will be assessed in a separate paper.

Treatment compliance and toxicity

Adjuvant treatment was started within 2 weeks of surgery for 157 patients (54 per cent), and within 1 month of surgery for 271 patients (94 per cent). There was a sigificant association between the occurrence of a postoperative complication and a delay of more than 2 weeks between surgery and the beginning of adjuvant therapy ($P=0.008$). However, postoperative complications were reported in only 55 patients (19 per cent) and thus could not explain the majority of delays in excess of 2 weeks. Treatment was continued after the 1-year protocol period in 89 patients (31 per cent), for periods up to three additional months (and for as long as 6 and 10 months in two patients).

Table 2 shows the reasons for stopping treatment in both groups. Sixty-one per cent of the patients completed therapy (1 year or more). Four patients refused therapy (all on levamisole) while toxicity prevented further administration in 14 (placebo, two; levamisole, 12). In the 12 patients who stopped taking levamisole, four had agranulocytosis (one with a white cell count as small as 1200 per mm^3 and with 10 per cent neutrophils), two had skin rashes, two had flu-like syndromes,

Table 2 *Reasons for stopping therapy*

	Placebo	Levamisole	Total (%)
End of 1 year treatment	90	87	177 (61)
Disease relapse	33	26	59 (21)
Death without relapse	6	2	8 (3)
Patient refused treatment	0	4	4 (1)
Treatment stopped due to toxicity	2	12	14 (5)
Major protocol violation	2	4	6 (2)
Patient lost to follow-up	6	6	12 (4)
Other reasons	7	2	9 (3)
Number of patients	146	143	289

two had depressive syndromes and two had nausea and vomiting. All patients returned to normal after stopping therapy. The two patients who stopped taking placebo did so because of nausea and vomiting.

The most frequently reported minor side-effects of treatment did not differ between the two treatment groups (*Table 3*).

Disease-free survival

Figure 1 shows the disease-free survival curves up to 7 years. There was no significant difference between the two treatment groups ($P=0{\cdot}53$). There was also no significant difference between the two treatment groups if the comparison was limited to patients in whom adjuvant therapy was initiated within 2 weeks of surgery ($P=0{\cdot}87$). Relapses were histologically confirmed in 67 (placebo, 35; levamisole, 32) of 157 cases (43 per cent). The sites of relapse are detailed in *Table 4*. Relapse occurred at the anastomotic site in 46 of 157 cases (29 per cent). The liver was the first site of relapse in 97 of 157 cases (62 per cent).

Survival

Figure 2 shows the survival curves up to 7 years. The percentage of patients still alive at 5 years was 39 per cent (standard error, 5·4 per cent) in the placebo group *versus* 51 per cent (standard error, 5·5 per cent) in the levamisole group. The difference between the survival curves was not statistically significant ($P=0{\cdot}35$). There was no difference between the two treatment groups if the comparison was limited to patients in whom adjuvant therapy was initiated within 2 weeks of surgery ($P=0{\cdot}86$). Exclusion of the ineligible patients and those who never started taking their treatment (placebo or levamisole), did not affect the survival comparisons ($P=0{\cdot}33$) Subset analyses and retrospective adjustments of the treatment comparisons were performed with the prognostic features of *Table 1*. No subset analysis or adjusted comparison resulted in significant separation of the treatment groups.

Table 3 *Number of patients affected by the most frequently reported side-effects of therapy*

	Placebo	Levamisole	Total (%)
Tiredness	27	29	56 (21)
Insomnia	19	18	37 (14)
Anorexia	20	15	35 (13)
Depression	15	19	34 (13)
Nausea and vomiting	10	20	30 (11)
Patients evaluable for toxicity	140	129	269

Discussion

Treatment compliance and toxicity

Treatment compliance was reported to be excellent (*Table 2*), but no measures were taken to verify that the patients had in fact taken their tablets Levamisole was generally well tolerated, as

Table 4 *Sites of relapse*

	Placebo	Levamisole	Total (%)
Site of relapse			
Anastomosis	30	16	46 (29)
Liver	46	51	97 (62)
Peritoneum	15	17	32 (20)
Lymph nodes	11	13	24 (15)
Lung	6	7	13 (8)
Pleura	2	2	4 (3)
Bone	6	2	8 (5)
Skin	7	0	7 (4)
Central nervous system	4	1	5 (3)
Number of relapses	82	75	157

Percentages are relative to the number of relapses, they do not add up to 100 per cent because of multiple relapse sites

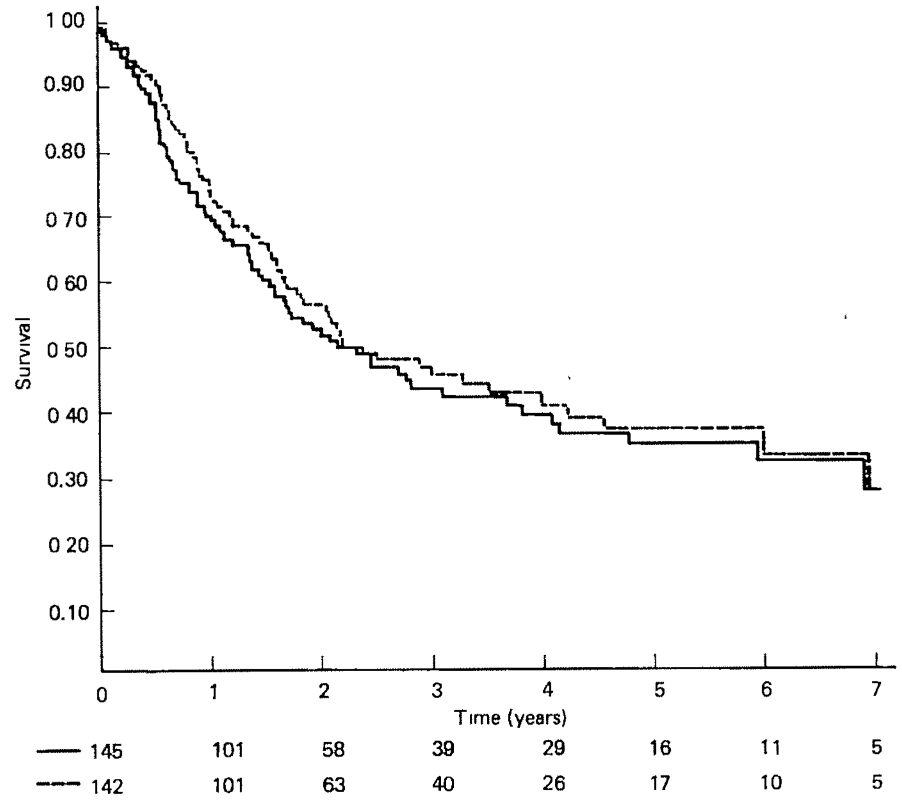

Figure 1 *Disease-free survival curve by treatment group.* ——, *Placebo total number of patients, 145, number of relapses, 82,* –––, *levamisole total number of patients 142, number of relapses, 75,* P=0 53 (*log rank test*)

	0	1	2	3	4	5	6	7
——	145	118	76	45	32	16	11	5
– – –	142	118	72	47	30	18	10	5

Figure 2 *Survival curve by treatment groups ——, Placebo total number of patients, 145, number of deaths, 66, – – –, levamisole total number of patients, 142, number of deaths, 55,* P = 0.35 *(log rank test)*

evidenced by the fact that minor side-effects were reported as frequently in the levamisole as in the placebo group (*Table 3*). Side-effects were considered minor by some authors[32–34], while for others they were an important drawback responsible for interruption of the treatment in over 21 per cent of the cases[35]. In our series, levamisole was stopped for toxicity in only 12 patients of 139 (9 per cent); two of these patients complained of nausea and vomiting, but placebo was also stopped in two other patients with similar complaints. Four of the patients in whom levamisole was stopped had reversible agranulocytosis. This was in line with previous experience with levamisole[33,36,37] None of the patients experiencing agranulocytosis was found to have an autoimmune disease, such as a rheumatoid disorder[38].

Therapeutic results

This trial failed to show a benefit of levamisole over placebo in terms of either disease-free survival or overall survival. This negative result does not exclude the possibility of a small beneficial effect of levamisole. More patients relapsed or died in the placebo group than in the levamisole group, and the observed 5-year survival is 12 per cent better in the levamisole group (51 *versus* 39 per cent). Under reasonable assumptions, this trial had an 80 per cent chance of detecting a difference in 5-year survival of about 18 per cent, and had less than an 80 per cent chance of detecting smaller differences which might none the less be of clinical relevance. However, the fact that the disease-free survival curves were identical in the levamisole and placebo groups (*Figure 1*) makes it unlikely that the difference observed in the survival curves (*Figure 2*) was attributable to any treatment effect, it is more likely to be due to chance fluctuations. In addition, patients with a less favourable prognosis (four or more positive lymph nodes) were by chance randomized to receive placebo, so that if anything the unadjusted treatment comparison may be somewhat biased in favour of the levamisole group.

Our negative result must be interpreted in the context of other clinical trials using similar therapeutic approaches. Few randomized control trials were published on adjuvant immunotherapy for colorectal cancer[14]. One trial compared fluorouracil and radiotherapy with the same regimen plus MER, in Dukes' B and C colorectal cancer; only 73 patients were randomized but the authors claim benefit of immunotherapy in the 44 patients with Dukes' C colon cancer[39,40]. Another trial comparing a control group with groups receiving either fluorouracil or fluorouracil + levamisole was so small, with 52 patients followed for at least 6 months, that its results cannot possibly show any effect[33]. Yet another trial of *C. parvum versus* control was too small to allow any meaningful conclusion (92 patients of whom 26 were Dukes' C)[41]. A large trial comparing four treatment groups consisting of chemotherapy with fluorouracil and semustine, or BCG alone, or both, or no adjuvant therapy was published by the Gastrointestinal Tumor Study Group in stages B_2 and C colon cancer[42]. No significant treatment differences were found among the 572 patients (of whom 340 were Dukes' C) in either recurrence or survival rates. A recently reported trial compared a control group with groups receiving either fluorouracil or fluorouracil + levamisole in Dukes' A, B or C colorectal cancer[43]. A significant survival advantage of fluorouracil + levamisole over both the control group and the group receiving fluorouracil alone was found in the 141 patients analysed, of whom 41 were Dukes' C.

Three further large clinical trials were reported recently, but in abstract form only. The North Central Cancer Treatment Group (NCCTG) compared a control group with groups receiving either levamisole alone or fluorouracil + levamisole in Dukes' B_2 or C colorectal cancer[34] Both arms containing levamisole were found to be superior to the control group in terms of time to progression and survival in the 39 patients analysed. The advantage of therapy was reported to be most striking in Dukes' C patients. The National Surgical Adjuvant Project for Breast and Bowel Cancers (NSABP) compared a control group with a group receiving polychemotherapy with fluorouracil, semustine and vincristine, and one receiving BCG alone in Dukes' B and C colon cancer[44]. In this large trial of

1166 patients, BCG administration resulted in no advantage in terms of disease-free survival but in a small yet significant prolongation of survival. The Southwest Oncology Group compared a control group with a group receiving chemotherapy with fluorouracil and semustine, and one receiving the same chemotherapy + BCG in Dukes' B_2 and C colon cancer[45]. There was no overall difference in either survival or relapse-free survival among the 626 patients randomized, though significant benefits of both chemotherapy and chemotherapy + BCG were claimed among the Dukes' B_2 and C_1 patients, but not among the stage C_2 patients.

On the basis of all these results it is not yet clear whether non-specific immunotherapy alone provides any significant benefit in poor prognosis colon cancer Significant benefits were reported mostly in patients receiving a combination of immunotherapy and chemotherapy. The respective impact of each is unclear and any synergism in the two approaches is a hypothesis that deserves further study. Benefits also tended to be reported in series of colorectal cancer patients, with no distinction made between colonic *versus* rectal locations. It is quite possible, though still speculative, that rectal lesions might respond better to therapy than colonic lesions[14] Our results confirm the experience of the Gastrointestinal Tumor Study Group and of the NSABP with a single immunotherapy (BCG) in colon cancer: the overall effect of therapy, if any, is probably small so that other adjuvant approaches must be considered[42,44]. Whether our results are at variance with those of the NCCTG is still an open question[34] A meta-analysis of all related clinical trials of immunotherapy in colorectal cancer will be most useful when the more recent trials are mature[14].

Our own series presented several advantages: first, it was relatively homogeneous, as only Dukes' C colon tumours were considered for inclusion in the trial. To control further for the remaining heterogeneity among the patients entered, careful examination of the resected tumours was performed and detailed data on histopathology were available for analysis of their prognostic influence. No analysis of treatment results in subgroups appeared to yield outstanding results, however. These analyses were not presented in this paper because we believe that in most instances they confuse rather than clarify the issue, given the great likelihood of spuriously large treatment effects occurring by chance in some of the subgroups examined[46].

Secondly, treatment was given in a double-blind manner, and therefore the possibility of bias in evaluating treatment results in terms of disease relapse was minimal. Because the assessment of relapses is often somewhat subjective (unless it is histologically confirmed, as was the case in less than half of the patients in our series), the possibility of bias must be borne in mind when evaluating the results of non-blinded trials.

Thirdly, the dose of levamisole was related to the weight of the patient in order to reach the optimal daily dose suggested by Amery[25], i.e. about 2·5 mg kg^{-1} day^{-1}. Treatment was initiated as soon as possible after surgery, taking into account the delays due to the histological classification of the resected specimen and/or any postoperative complications. Treatment was started within 2 weeks of surgery for more than half of the patients. Timing could have been important, because levamisole administration can partially reverse the depression of the cell-mediated immunity observed immediately after surgery[47]. However, no significant effect of levamisole was seen on survival or disease-free survival in the patients who started receiving the adjuvant therapy within 2 weeks of surgery Thus the lack of a significant benefit of levamisole in the present study was probably independent of the early or delayed administration of the drug. Furthermore, it can be argued that depression of the immune response is not confined to the immediate postoperative period in cancer patients so that levamisole could potentially have acted on the immune response throughout the entire period of administration.

Finally, treatment consisted only of immunotherapy, with no concurrent chemotherapy. Thus no interaction between the immune modulation and other cellular mechanisms (e.g. cytotoxicity) could have obscured or enhanced any possible benefit of the administration of levamisole.

A common pathophysiology for full thickness rectal prolapse, anterior mucosal prolapse and solitary rectal ulcer

Anorectal pressures at rest, during conscious contraction of the external sphincter, during serial distension of the rectum and during straining to inflate a balloon were measured in 56 patients (21 patients with full thickness rectal prolapse, 24 patients with anterior mucosal prolapse, 11 patients with solitary rectal ulcer) and in 30 normal subjects. Both basal and squeeze pressures were significantly lower in the three groups of patients compared with matched normal controls ($P<0{\cdot}05$)*. During increases in intra-abdominal pressure, anal pressure remained above maximum rectal pressure* ($P<0{\cdot}05$) *in normal controls, with the highest anal pressures being recorded in the most caudal anal channels. In contrast, anal pressures tended to be lower than rectal pressures during this manoeuvre in patients with rectal prolapse, anterior mucosal prolapse and solitary rectal ulcer, and the highest pressures were recorded in the channels nearest the rectum. During serial distension of the rectum, 64 per cent of patients with solitary rectal ulcer, 75 per cent with anterior mucosal prolapse and 76 per cent with rectal prolapse, but only 10 per cent of controls, showed repetitive rectal contractions. The highest anal pressure always remained higher than rectal pressure during rectal distension in normal subjects* ($P<0{\cdot}05$) *but not in patients. The threshold rectal volume required to cause a desire to defaecate and the maximum tolerable volume were significantly lower* ($P<0{\cdot}05$) *in each of the patient groups, compared with normal subjects. The similarity in the results from patients with rectal prolapse, anterior mucosal prolapse and solitary rectal ulcer support the hypothesis that they share a common pathophysiology. In each of the groups, the rectum is hypersensitive and hyper-reactive, and weakness of the anal sphincter creates the conditions for prolapse of the rectum to occur into or through the anal canal.*

Keywords: Solitary rectal ulcer, anterior mucosal prolapse, full thickness rectal prolapse, rectum, anal sphincter, electromyography

Professor N. W Read

Anterior mucosal prolapse and solitary rectal ulcer are often found in association[1–5] Their pathogenesis is not understood, though it is often assumed that redundant anterior rectal mucosa enters and plugs the anal canal preventing normal defaecation and inducing anal discomfort and a feeling of incomplete evacuation[4]. Solitary rectal ulcer is thought to occur when the redundant mucosa becomes traumatized and ischaemic within the anal canal[1]. Surgical treatment of anterior mucosal prolapse is often aimed at fixation of the mucosa to the rectal wall by injections of sclerosant or by resection of the redundant rectal mucosa[4], although rectopexy may be preferable for solitary rectal ulcer Although such treatments may be effective in the short term, their long-term benefits are poor[6,7]. It has been suggested that anterior mucosal prolapse may progress to full thickness rectal prolapse[8]. The latter is also associated with 27–49 per cent of cases of solitary ulcer[8–10]. These three conditions may therefore share a common pathophysiology. In support of this suggestion, patients with full thickness rectal prolapse, anterior mucosal prolapse, or solitary rectal ulcer often complain of incontinence[6,11], usually have abnormal descent of the pelvic floor on straining[12,13] and show electrical evidence of reinnervation of the external anal sphincter[11,12,14].

The aims of these series of experiments were to provide further insights into the pathophysiology of the three conditions and to test the hypothesis that each might represent different stages in the same pathophysiological process. Manometric and electrophysiological measurements were carried out under resting conditions, during a voluntary squeeze, during distension of the rectum with a balloon and during increases in intra-abdominal pressure produced by asking the subjects to inflate a balloon.

Patients and methods

Patients

Studies were carried out on a total of 54 women, aged between 22 and 86 years (median 60 years) Nine patients (aged 22–73 years, median 53 years) had a solitary rectal ulcer which was defined as a discrete area of ulceration on the anterior rectal mucosa which showed the typical histological features[5,10,15] Twenty-four patients (aged 34–78 years, median 55 years) had anterior mucosal prolapse, which was identified at proctoscopy as redundant anterior rectal mucosa which appeared at the anal margin if the patient strained Twenty-one patients (aged 38–86 years, median 72 years) had an overt full thickness rectal prolapse extending beyond the anal verge All patients tested showed evidence of abnormal perineal descent in that the pelvic floor descended to more than 2 cm below the pubococcygeal line when the patient strained[14]. Seventy-two per cent (67 per cent solitary rectal ulcer, 71 per cent anterior mucosal prolapse, 76 per cent rectal prolapse) of these patients had had vaginal deliveries, and 35 per cent (33 per cent solitary rectal ulcer, 38 per cent anterior mucosal prolapse, 33 per cent rectal prolapse) had

0007–1323/89/030290–06$3.00 © 1989 Butterworth & Co (Publishers) Ltd

had more than three children. Twenty-eight per cent of the patients (33 per cent solitary rectal ulcer, 29 per cent anterior mucosal prolapse, 24 per cent rectal prolapse) were nulliparous. Two men with solitary rectal ulcer (aged 29 and 33 years) were also studied Six patients with anterior mucosal prolapse (25 per cent), four patients with solitary rectal ulcer (36 per cent) and 14 patients (67 per cent) with rectal prolapse also complained of faecal incontinence

For comparison, tests were also carried out on 20 normal female subjects (aged 26–54 years, median 43 years) and ten normal male subjects (aged 19–40 years, median 23 years) None of these subjects suffered from faecal incontinence or had any disease of the anal sphincter or the colon.

All subjects and patients gave their written informed consent for the study The protocol was approved by the Ethical Subcommittee of the Sheffield Health Authority

Methods

A complete history was taken from each patient Careful digital, sigmoidoscopic and proctoscopic examinations of the anorectum were conducted The degree of perineal descent was assessed by proctography[14] or by perineometry[16]. All patients and controls underwent dynamic tests of anorectal function using simultaneous multiport manometry and external sphincter electromyography (EMG) No bowel preparation was used before the test, although patients were invited to empty the rectum if they felt the need to do so.

With the subject lying in the left lateral position and the hips flexed to 90°, a seven lumen polyvinyl catheter, which had an external diameter of 4 mm and which terminated in a small latex balloon, was inserted into the anal canal so that manometric side-holes were situated in the anal canal at 0·5, 1, 1·5, 2 and 2 5 cm and in the rectum at 4·5 cm from the anal verge, the balloon was situated 8 cm from the anal margin. The side-holes were perfused with water at a rate of 0 4 ml/min using a low compliance pressurized perfusion system (Mui, PIP2, Mississauga, Toronto, Canada). Pressures were recorded by pressure transducers (Statham, 230B, Oxnard, California, USA), which were situated in each infusion line and connected via amplifiers to a chart recorder (Hewlett-Packard Co., Waltham, Massachusetts, USA)

The electrical activity of the external anal sphincter was measured using a bipolar wire electrode which was inserted without anaesthetic through the skin into the superficial aspect of that muscle[17,18] The EMG signal was integrated, and both raw and integrated records were displayed on the chart recorder.

Protocol

Resting sphincter pressures and electrical activity were measured for 15 min, during which time the pressures gradually fell in the outermost anal channels The pressures in the anal canal at the beginning and the end of the 15-min period were recorded as the maximum and minimum basal pressures respectively The subject was then instructed to contract the external sphincter as strongly as possible and to maintain the contraction for at least 20 s This was repeated on two further occasions with a rest period of 1 min between each contraction After a gap of at least 5 min, the rectal balloon was inflated with increasing volumes of air (10, 20, 40, 60 and 100 ml). Each inflation was maintained for 1 min, whereupon the balloon was deflated and a gap of at least 1 min was allowed before the next inflation The presence or absence of transient sphincter relaxation, an increase in activity of the external anal sphincter or an increase in rectal pressure were noted. An index of external anal sphincter activity during rectal distension was calculated by multiplying the voltage of electrical activity by the duration of its activity. During each distension, subjects were asked to report if they perceived the distension and to grade the sensation as a feeling of wind, a feeling of stool in the rectum, a desire to defaecate, an urgent desire to defaecate, or pain

The subject was allowed to rest for at least 5 min and was then instructed to increase the intra-abdominal pressure by blowing up a balloon This was carried out on three occasions separated by a rest period of 1 min, and the anorectal pressures and electrical activity of the external anal sphincter were recorded. Any leakage of fluid or faeces that took place during this manoeuvre was noted

Statistical analysis

An analysis of variance was used to test for differences in sphincter pressure and responses to rectal distension and increases in intra-abdominal pressure among the groups If the analysis of variance showed statistical significance, the Student's *t* test was used to determine the levels of significance. The χ^2 test was used to compare the percentage of subjects in each group that showed anal relaxation and repetitive rectal contractions during rectal distension

Results

Basal and sphincter squeeze pressures

After insertion of the catheter, the basal pressure fell slowly to a stable low level over 15 min. The maximum basal pressures recorded shortly after insertion of the catheter ($P < 0{\cdot}01$) and the maximum squeeze pressures ($P < 0{\cdot}01$) at all anal ports were significantly lower in patients with rectal prolapse, anterior mucosal prolapse and solitary rectal ulcer than in normal subjects (*Figure 1*). The minimum basal pressures were also significantly lower in all patient groups compared with normal subjects (*Figure 1*), but only at 1 and 0·5 cm from the anal margin ($P < 0{\cdot}05$). Patients with full thickness rectal prolapse had significantly lower maximum basal pressures than patients with solitary rectal ulcer and anterior mucosal prolapse, though there were no significant differences in maximum squeeze pressures or minimum basal pressures between these groups. Men with solitary rectal ulcer also showed abnormally low maximum basal pressures (34 cmH_2O and 52 cmH_2O, normal range 51–113 cmH_2O) and maximum squeeze pressures (126 cmH_2O and 170 cmH_2O, normal range 178–308 cmH_2O) compared with men in the control group.

Anorectal pressure responses to rectal distension

Distension of the rectal balloon in normal subjects usually caused reductions in pressure at all anal ports (*Figure 2a*), increasing in amplitude and duration as the distending volume increased. These anal relaxations were associated with increases in rectal pressure and transient increases in the electrical activity of the external anal sphincter that became more prolonged as the distending volume and duration of relaxation increased The anal pressure recorded during balloon distension was termed the residual pressure and lowest values always occurred at distension volumes ≥ 60 ml. On deflating the balloon, the anal pressure often showed a rebound increase to values that exceeded the preinflation pressure. Although the rebound was occasionally associated with a brief increase in the electrical activity of the external anal sphincter, it always exceeded the latter in duration, suggesting that it was caused predominantly by increased activity in the internal sphincter. The amplitude of the rebound pressure increased as distending volume increased, and thus resulted in increases in the anal pressures occurring before the next inflation (preinflation pressures)

Rectal distension with increasing volumes of air decreased anal sphincter pressure in all normal subjects and in all patients with solitary rectal ulcer, but in only 10 per cent of patients with rectal prolapse and 30 per cent patients with anterior mucosal prolapse ($P < 0{\cdot}02$, compared with either controls or solitary rectal ulcer) The absent anal relaxation during rectal distension was associated with very low preinflation pressures and hence the observation suggested impaired internal sphincter function. When anal relaxation was seen in patients with the three conditions, this took place at higher volumes of distension, when the rebound phenomenon increased the pressure immediately before the next inflation

Most of the patients with rectal prolapse and anterior mucosal prolapse showed increases in anal pressures during rectal distension (*Figure 2b*) These increases in pressure were associated with bursts of activity in the external anal sphincter. External anal sphincter indices were significantly higher ($P < 0{\cdot}05$) in patients with solitary rectal ulcer and anterior mucosal prolapse than in controls during rectal distension with volumes of 10–100 ml and in patients with rectal prolapse during rectal distension with volumes of 10 and 20 ml (*Figure 3*), but despite this the residual anal pressures were no higher in any of the patient groups compared with the controls (*Table 1*)

The highest preinflation and rebound anal pressures were significantly higher in normal subjects than in each of the patient groups ($P < 0{\cdot}05$, *Table 1*) Normal subjects showed a gradient in residual pressures increasing towards the outermost channels. This gradient was not present in women with solitary rectal ulcer and rectal prolapse and men with solitary rectal ulcer. The

Channels 1–6 represent ports situated 0·5, 1·0, 1·5, 2·0, 2·5 and 4·5 cm from the anal margin. Patients with rectal prolapse showed abnormally low anal pressures before rectal distension, and during rectal distension they showed a prolonged increase in anal pressure caused by increased activity in the external anal sphincter, repetitive rectal contractions and greater rectal sensitivity. The bars* (⊔) *indicate when subjects experienced rectal sensations. DD, desire to defaecate,* +, ++ *and* +++ *indicate the severity of the sensation. EMG, electromyogram*

highest anal pressure always remained above the highest rectal pressure during rectal distension in normal subjects, but was consistently lower than rectal pressures at all volumes of distension in patients with rectal prolapse and became lower in patients with anterior mucosal prolapse and solitary rectal ulcer as the rectal volume increased (*Figure 4*).

Sixty-four per cent of patients with solitary rectal ulcer, 75 per cent with anterior mucosal prolapse, 76 per cent with rectal prolapse, but only 10 per cent of normal volunteers ($P<0{\cdot}05$), showed repetitive rectal contractions during rectal distension (*Figure 2b*).

The differences in the responses to rectal distension between men with solitary rectal ulcer and men in the control group were similar in all respects to those seen between women with solitary rectal ulcer and women in the control group.

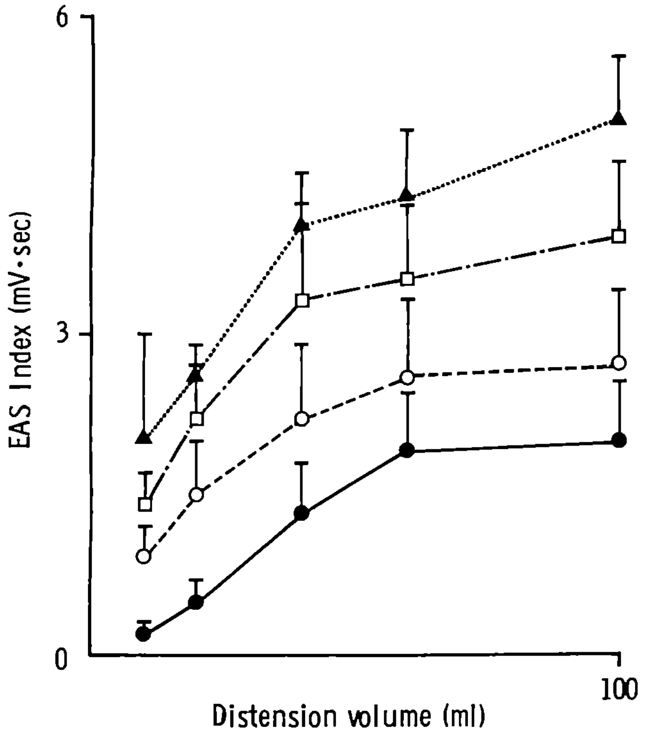

Figure 3 *External anal sphincter index during inflation of a rectal balloon with volumes of 10–100 ml in patients with solitary rectal ulcer (▲), anterior mucosal prolapse (□) and rectal prolapse (○), and in normal subjects (●). External anal sphincter indices were significantly higher ($P<0{\cdot}05$) in patients with solitary rectal ulcer and anterior mucosal prolapse at all volumes of distensions, and in patients with rectal prolapse at 10 and 20 ml Results are shown as mean ±s e m.*

Rectal sensitivity

The distending volume at which the rectal balloon was first perceived and at which subjects complained of a feeling of wind were not significantly different between the groups. The lowest volume required to cause a desire to defaecate and the maximum tolerable volume, however, were significantly higher in normal subjects than in patients, but there were no significant differences in these values between the patient groups (*Table 2*).

Anorectal changes during increases in intra-abdominal pressure

When normal subjects increased their intra-abdominal pressure by blowing up a balloon, this was accompanied by increases in

Anal pressures always remained above ($P<0{\cdot}05$) rectal pressures in normal subjects, were consistently lower ($P<0{\cdot}05$) than rectal pressures in patients with rectal prolapse, and became lower as the rectal volume increased in patients with anterior mucosal prolapse and solitary rectal ulcer Results are expressed as mean ±s e.m. * Significant difference between anal and rectal pressure ($P<0{\cdot}05$)*

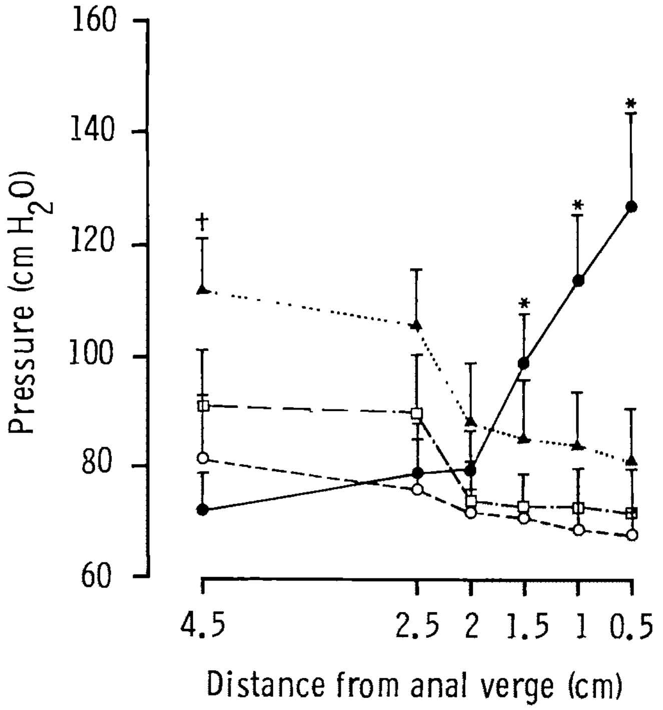

Figure 5 *The highest pressures in the rectum (4·5 cm from the anal verge) and the anal canal when normal subjects (●), patients with solitary rectal ulcer (▲), anterior mucosal prolapse (□) and rectal prolapse (○) increased their intra-abdominal pressure by inflating a balloon Results are expressed as mean ±s e m *Anal pressure was higher in normal subjects than in each of the patient groups* ($P<0{\cdot}001$) *† Rectal pressure in patients with solitary rectal ulcer was higher than in normal subjects* ($P<0{\cdot}05$)

rectal pressure, anal pressures and in the electrical activity in the external anal sphincter The pressures in the more distal anal canal in normal subjects during increases in intra-abdominal pressures were always higher than the rectal pressure (*Figure 5*). Patients with rectal prolapse, solitary rectal ulcer and anterior mucosal prolapse showed similar increases in rectal pressure during increases in intra-abdominal pressure and all demonstrated increased electrical activity of the external sphincter. However, their anal pressures during this manoeuvre were much lower than in normal subjects particularly in the more distal anal channels (*Figure 5*) ($P<0{\cdot}001$), and remained below rectal pressure ($P<0{\cdot}05$), creating in every patient a pressure gradient that would favour incontinence or prolapse The rectal pressure in patients with solitary rectal ulcer was significantly higher ($P<0{\cdot}05$) than in normal subjects and patients with rectal prolapse Men with solitary rectal ulcer also showed the same pattern with lower anal pressures (163 cmH_2O and 87 cmH_2O, normal range 138–367 cmH_2O) and higher rectal pressures (184 cmH_2O and 155 cmH_2O, normal range 52–152 cmH_2O) than in the control group

None of the normal subjects leaked fluid or faeces when they strained to blow up the balloon In contrast, 61 per cent (33 per cent solitary rectal ulcer, 46 per cent anterior mucosal prolapse, 90 per cent rectal prolapse) of the patients leaked, and when this occurred the rectal pressure was always higher than the highest anal pressure.

Discussion

These studies have shown that the anal pressures in patients with full thickness rectal prolapse, anterior mucosal prolapse and solitary rectal ulcer are much lower than in normal subjects Both basal and squeeze pressures are abnormally low, suggesting weakness in both the external and internal sphincters in these conditions. The weakness of the internal sphincter is particularly obvious in patients with rectal prolapse (full thickness rectal prolapse or anterior mucosal prolapse) who have very low anal pressures before and after rectal distension and no anal relaxation. The weakness of the sphincter could explain why so many patients with anterior mucosal prolapse and rectal prolapse suffer from faecal incontinence[19,20].

When normal subjects increased their intra-abdominal pressure in order to blow up a balloon, a compensatory increase in external sphincter activity was associated with a rise in anal pressure above the rectal pressure, creating a pressure barrier that preserved continence. Indeed no leakage of the fluid, infused via the manometric channels, was observed in normal subjects during rises in intra-abdominal pressure. A similar increase in the electrical activity of the external sphincter occurred in all three patient groups during increases in intra-abdominal pressure, and this was greater than that seen in normal subjects, confirming recent data from Womack and colleagues in solitary rectal ulcer patients[21]. However, this enhanced electrical discharge was not associated with higher anal pressures, even though the pressure profile resembled the EMG profile, suggesting it was produced by activity of the external sphincter In fact, the anal pressures did not increase above the rectal pressure in any of the patients, creating conditions that would favour prolapse and incontinence, and caused leakage of infusion fluid during this manoeuvre in 61 per cent of patients. This association between increased electrical discharge and low pressures suggests muscle weakness which may be due to a variety of causes—myopathy, neuropathy or trauma. The observations that these patients all have perineal descent[12,14] and abnormal motor unit potentials[12], however, implicates pudendal neuropathy[11,14] as a major cause of sphincter weakness. Patients with solitary rectal ulcer showed higher rectal pressures during increases in intra-abdominal pressure than patients with prolapse and normal subjects confirming recent observations by Womack *et al.*[21] Thus, we would agree with these authors that solitary rectal ulcer probably represents an early stage in the development of procidentia, where the rectal mucosa prolapses into and plugs the anal canal resulting in higher rectal pressures during straining than in conditions in which the rectum is sufficiently mobile to prolapse out of the anus Womack and his colleagues suggest[21] that ulceration is probably caused by the high transmural pressure gradient in the prolapsing rectum, leading to distension and rupture of submucosal blood vessels and consequent ischaemia of the rectal mucosa[21].

A similar pattern of results was seen in response to rectal distension. All patients showed an increase in external anal sphincter electrical activity in response to rectal distension, and this activity was enhanced in all three groups of patients. The pressures generated during rectal distension, however, were lower than those recorded during the same degrees of distension in normal subjects and, unlike normal subjects, the anal pressures were lower than rectal pressures during rectal distension, creating the conditions for incontinence to occur In addition, the responses to rectal distension indicate enhanced rectal sensitivity and reactivity in all three patient groups Patients perceived the desire to defaecate at much lower volumes than normal subjects and were much more likely to develop rectal contractions in response to rectal distension, causing the rectal pressure to rise above the anal pressure and threatening continence This rectal 'irritability' may in part be secondary to the inflammation caused by prolapse or rectal ulceration and thus similar to the situation found in patients with ulcerative colitis[22] In support of this suggestion, postoperative follow-up studies carried out in one patient whose solitary ulcer had healed showed an increase in the volume required to induce a desire to defaecate and disappearance of the repetitive rectal contractions in response to rectal distension, but no change in the low sphincter pressure.

The increased rectal sensitivity may encourage the subject to attempt to strain when very small volumes are present in the rectum, causing the rectum to prolapse into the weak anal canal. At first only the part of the rectum lying immediately above the anal canal would prolapse (anterior mucosal prolapse), but this may be sufficient to redouble straining efforts[19,23], enhancing the prolapse and exacerbating pelvic floor descent and leading to further neuropathic weakness of the external anal sphincter; this would eventually result in full thickness rectal prolapse. Our observation that the median age of patients with rectal prolapse was two decades later than the median age of patients with solitary rectal ulcer and with anterior mucosal prolapse confirms previous data[24] and would support this proposed development.

In summary, our results suggest that full thickness rectal prolapse, anterior mucosal prolapse, and solitary rectal ulcer may represent different stages of the same basic condition which is associated with a combination of a very weak anal sphincter and an abnormally irritable rectum. The cause of the external sphincter weakness in many of these patients is probably related to pudendal neuropathy, since they all had perineal descent, and previous studies on a similar group of patients showed evidence of reinnervation of the external sphincter, suggesting neuropathic damage to the sphincter[11,12,14,25]. The reason for the concomitant weakness of the internal sphincter is unclear but could possibly be due to traction on the delicate sympathetic nerve supply. The fact that patients in these groups have abnormal descent of the pelvic floor suggests that either failure of the levators to contract and support the pelvic floor during increases in intra-abdominal pressure, and/or stretching and weakness of the connective tissue fascia may initiate the changes in sphincter function observed in this study. Pelvic floor weakness is common after childbirth and this may explain the high female preponderance in this group, although it is important to note that two patients in our group were men and that 15 of the women were nulliparous

Thigh length versus knee length stockings in the prevention of deep vein thrombosis

M. J. LeF. Porteous, E. A. Nicholson, L. T. Morris, R. James and D. Negus

United Medical and Dental Schools of Guy's and St. Thomas's, Lewisham Hospital, London SE13 6LH, UK

Correspondence to: Mr D. Negus

Above-knee graduated compression stockings are effective in preventing postoperative deep vein thrombosis, but are more expensive and less acceptable than below-knee stockings. One hundred and fourteen patients undergoing major abdominal surgery were randomly allocated to wear above-knee or below-knee graduated compression stockings. Deep vein thromboses were diagnosed by isotope uptake in three of 56 patients (5·4 per cent) in the above-knee group and one of 58 patients (1·7 per cent) in the below-knee group. These differences are not statistically significant. Results suggest that below-knee stockings are as effective as above-knee in the prevention of postoperative deep vein thrombosis.

Keywords: Deep vein thrombosis, ^{125}I-labelled fibrinogen uptake, graduated compression stockings

Effective methods of preventing postoperative deep venous thrombosis include low dose heparin[1,2], low molecular weight dextran[3], intermittent pneumatic compression[4] and graduated compression stockings[5] The latter have the advantages of simplicity, safety and economy.

Wilkins *et al.* (1952) demonstrated that thigh length graduated compression stockings effected a significant reduction in clinically detected pulmonary embolism[6] and, since then, similar stockings have been shown to be effective in reducing the incidence of isotope detected deep vein thrombosis.[7,8]

Knee length (below-knee) stockings are cheaper than thigh length (above-knee) and are more acceptable to patients and nurses, but apart from the study by Tsapogas and his colleagues[9], there has been no previous investigation of their value in preventing postoperative deep vein thrombosis Most deep vein thromboses which follow major abdominal surgery originate in the calf veins[10], and thigh length stockings effect no greater increase in femoral vein blood flow velocity than knee length[11], These observations suggest that knee length stockings will effectively prevent postoperative deep vein thrombosis.

This paper reports the results of a randomized clinical trial comparing the effectiveness of knee length with that of thigh length stockings

Stocking pressures

Lightweight graduated compression stockings (Brevet Hospital Products, Reading, UK) were used throughout the trial. As TED 'Anti Embolism' stockings (Kendall Company (UK) Ltd, London, UK), were used in most previous trials, the pressure profiles of each were compared on healthy volunteers (six legs), using the Borgnis Medical Stocking Tester[12].

Brevet above-knee stockings exerted a higher pressure at the ankle than TED above-knee stockings (Brevet 11 3 mmHg (s.d. ±2·8); TED 9 9 mmHg (s.d ±2·5)), but there was no significant difference in the pressures exerted by each type of stockings at calf or thigh level.

Patients and methods

Informed volunteers over 40 years of age undergoing major abdominal surgery were allocated (by random numbers) to be fitted with above-knee or below-knee Brevet graduated compression stockings on the morning of operation by the same surgical fitter Patients with varicose veins, a past history of deep vein thrombosis or myocardial infarction, premenopausal females and patients undergoing peripheral vascular surgery were excluded.

Stockings were worn until discharge No other method of deep vein thrombosis prophylaxis was used, but leg movement in bed was encouraged, and early mobilization was routine.

Detection of deep vein thrombosis was by ^{125}I-labelled fibrinogen uptake, ^{125}I-labelled fibrinogen was injected intravenously immediately postoperatively and leg scanning was performed on alternate days until discharge Deep vein thrombosis was diagnosed if the count at any point on the leg was 20 per cent greater than adjacent points or the corresponding point on the opposite leg, and if this difference persisted or increased in the subsequent 24 h. (In a previous study ^{125}I-labelled fibrinogen uptake achieved a false positive rate of 7 per cent and a false negative rate of 0 per cent by comparison with phlebography[13]. Phlebography was performed in all but one case with suspected deep vein thrombosis.

Results

One hundred and twenty-four patients were recruited for the trial. Of these, four from the above-knee, and six from the below-knee stocking group were subsequently withdrawn (five ratemeter failures, two inappropriate operations, one patient given heparin, one not fitted with stockings and one unable to tolerate stockings)

One hundred and fourteen patients (56 above-knee and 58 below-knee), were retrospectively matched for the following risk factors sex, malignant disease, cigarette smoking, and pelvic and emergency (i.e. non-elective) surgery, using the χ^2 test, and age, weight, preoperative haemoglobin, duration of anaesthetic, total volume of intravenous saline, time to ambulation and time to discharge, using the *t* test for unmatched pairs (*Table 1*). There was no statistical difference between the groups apart from age and preoperative haemoglobin. The above-knee group were slightly older than the below-knee group and the preoperative haemoglobin was higher in the below-knee group. Both groups of patients underwent similar operations (*Table 2*).

A total of four deep vein thromboses were detected. In the below-knee group calf thrombosis was detected in one patient (1·7 per cent), a 66-year-old woman undergoing emergency laparotomy. This thrombus was clinically overt. Three deep vein thromboses were detected in the above-knee group (5·4 per cent), two were without physical signs, in men aged 75 and 79 years, the former undergoing repair of a large incisional hernia and the latter a cholecystectomy with exploration of the common bile duct for obstructive jaundice. The third patient was a 72-year-old woman undergoing routine cholecystectomy;

the deep vein thrombosis was clinically overt. There was no statistical difference in the incidence of deep vein thrombosis between the two groups of patients using Fisher's exact probability test. The retrospective exclusion of all patients undergoing emergency surgery, including the one patient in each group who developed a deep vein thrombosis, does not affect this result.

One patient had a superficial thrombophlebitis detected; she was a 70-year-old woman in the above-knee group. Phlebography showed no evidence of deep vein thrombosis.

Below-knee stockings had a number of practical advantages. They were more acceptable than above-knee stockings to patients (especially men), and to the nursing staff. They were also more comfortable and showed no tendency to roll down and produce a garter like band round the leg.

Discussion

These results support the hypothesis derived from the work of Lawrence and Kakkar[11], that above-knee stockings have no advantages over below-knee stockings in the prophylaxis of postoperative deep vein thrombosis.

The deep vein thrombosis rate in these patients was lower than expected; however, three recent studies using above-knee stockings have reported similar or lower rates of deep vein thrombosis[8,14,15], while the only previous work using below-knee stockings, reported a deep vein thrombosis rate of 4 per cent[9].

This study contained too few patients undergoing emergency and pelvic surgery for any conclusions to be drawn from the fact that two of the former and none of the latter group developed a deep vein thrombosis. We recognize that the exclusion of patients undergoing emergency surgery lowers the incidence of deep vein thrombosis in the remaining patients; however, it does not alter the statistical result.

A recent report of two cases of lower limb ischaemia has emphasized the danger of above-knee stockings rolling down and producing a tourniquet effect[16] and suggests that below-knee stockings are safer, particularly in the elderly.

The advantages of patient comfort and safety, and of economy, indicate the need for further large-scale trials to evaluate the place of below-knee graduated compression stockings in the prophylaxis of postoperative deep vein thrombosis.

Table 2 *Operations performed*

The role of thrombolytic therapy in surgical practice

K. T. Moran,
E. R. Jewell and
A. V. Persson

Section of Peripheral Vascular Surgery, Lahey Clinic Medical Center, 41 Mall Road, Burlington, Massachusetts 01805, USA

Correspondence to:
Dr E. R. Jewell

The ability of streptokinase and urokinase to lyse intravascular fibrin-based clots is firmly established. However, there is a lack of enthusiasm for these agents because of serious haemorrhagic complications and a lack of controlled randomized studies indicating their efficacy. Thrombolytic therapy is suitable in only 15 per cent of patients with acute deep venous thrombosis. It restores the venous circulation to normal in up to 95 per cent of these patients if therapy is instituted within 5 days of the onset of symptoms. These patients have significantly fewer symptoms on follow-up than patients treated with heparin although the ability of thrombolytic therapy to preserve venous valvular function and to prevent the post-phlebitic syndrome is now in question. Thrombolytic therapy is as effective as heparin in preventing pulmonary embolism and may be superior in its treatment. Pulmonary haemodynamics are rapidly improved, diffusion capacity is restored and, although the evidence is inconclusive, long-term pulmonary hypertension may be prevented. Although the mortality rate is not decreased, controlled studies show that thrombolytic therapy may be beneficial in massive pulmonary embolism with clinical shock. Thrombolytic therapy is indicated for acute arterial and acute bypass graft occlusion when the surgical alternative is associated with a higher morbidity and mortality. Partial thrombolysis is achieved in up to 90 per cent of cases and the need for further therapeutic intervention is eliminated in one-third of the patients treated. New thrombolytic agents with greater specificity and potentially greater efficacy and fewer complications are being developed. Tissue plasminogen activator has been successfully used. Prourokinase, fibrin-seeking urokinase and acetylated streptokinase–plasminogen complex may expand the role of thrombolytic therapy in surgical practice.

Keywords: Fibrinolytic therapy, thrombolytic therapy, streptokinase, urokinase, tissue-type plasminogen activator

The role of thrombolytic therapy in surgical practice is controversial with some authors enthusiastically advocating its use while others consider it a therapy 'whose time has passed'[1,2]. In this review we will discuss the clotting mechanism, the fibrinolytic system, the various thrombolytic agents currently available, the indications for thrombolytic therapy, the potential benefits and risks of this therapy, the therapeutic regimens used and the use of adjunctive anticoagulation

The clotting mechanism

The *in vivo* action of the clotting mechanism is balanced by limiting reactions that normally prevent clots from developing in uninjured vessels. When endothelium is disrupted, collagen is exposed attracting platelets which adhere and liberate serotonin and adenosine diphosphate. Platelet aggregation ensues. A temporary loose plug is formed. This is converted into the definitive clot by fibrin in a reaction which requires calcium ions and is catalysed by factor XIII The fundamental reaction in the clotting of blood is conversion of the soluble plasma protein fibrinogen to insoluble fibrin in a reaction catalysed by thrombin. Thrombin is a serine protease that is formed from prothrombin by the action of activated factor X.

Factor X can be activated by reactions that proceed along either an intrinsic or an extrinsic pathway. The initial reaction in the intrinsic pathway is the activation of factor XII when blood is exposed to the collagen fibres underlying the endothelium in blood vessels. Factor XII activates factor XI which activates factor IX. In the presence of factor VIII and platelets, active factor IX activates factor X The extrinsic system involves the activation of factor VII by tissue thromboplastin, a protein–lipid complex released from blood vessel walls and a variety of other tissues when they are damaged. Active factor VII then activates factor X.

The fibrinolytic system

The physiological fibrinolytic system (*Figure 1*) maintains the patency of the circulation by dissolving the fibrin network of arterial and venous thrombi The primary fibrinolytic enzyme plasmin is formed by the activation of plasminogen, a normal circulating constituent of plasma Plasminogen has a strong affinity for fibrin and when intravascular thrombi are formed plasminogen becomes bound to fibrin[3]. During normal physiological fibrinolysis, tissue plasminogen activator is released from vascular endothelium and activates the fibrin-bound plasminogen Release of the plasminogen activator may be achieved by a wide variety of stimuli including venous occlusion, ischaemia, strenuous exercise, emotional stress, surgery, and local or systemic administration of vasoactive agents such as catecholamines, nicotinic acid and vasopressin analogues[4,5]. The result is a selective localized fibrinolysis[3,6,7]. A systemic lytic state is avoided and fibrinogen, prothrombin, factors V and VIII are unchanged[3,6,7]

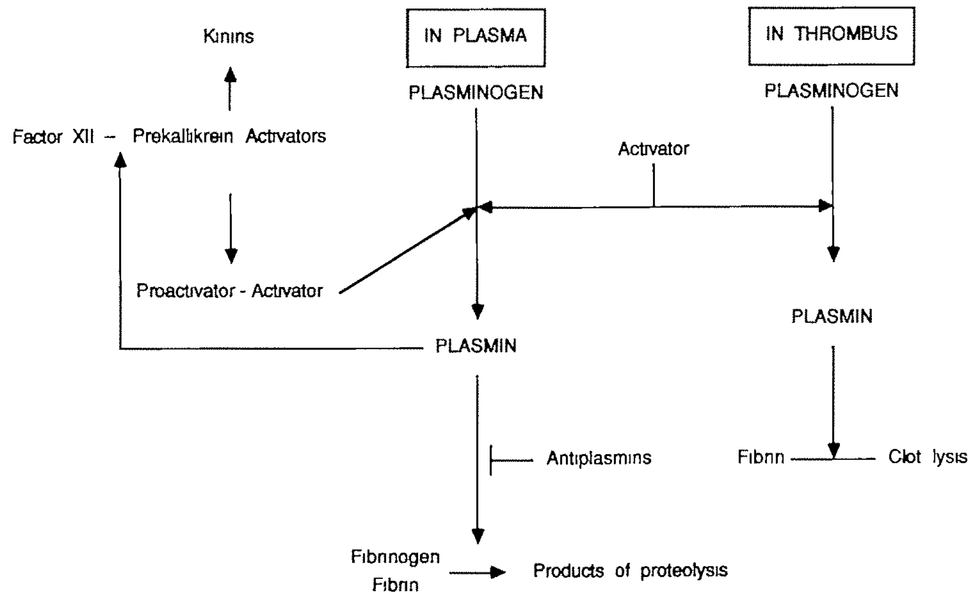

Figure 1 *The fibrinolytic system*

Circulating blood contains a number of inhibitors of fibrinolysis which under physiological conditions maintain a homoeostatic balance with active enzymes. These inhibitors inactivate plasmin once it is formed[8] They include α_1-antitrypsin, α_2-plasmin inhibitor, antithrombin-3 and α_2-macroglobulin Inhibitors of fibrinolysis have also been described in a number of body tissues, particularly platelets. In addition to exhibiting a weak antiplasmin effect, platelets were found to contain inhibitors of plasminogen activators including urokinase[9,10].

Agents that are capable of accelerating the fibrinolytic system are of interest to the surgeon because they have the potential to decrease the morbidity and mortality associated with thrombotic conditions. All agents in clinical use activate plasminogen rather than depolymerize fibrin directly[11]. Plasminogen is available from three sources: (a) trapped in the clot, (b) circulating in the plasma and (c) produced by the liver and entering the circulation after a thrombolytic agent has been administered[11,12].

This has important implications for the use of thrombolytic therapy[11,12]. Injecting the drug directly into a clot would convert only the trapped plasminogen. To create a systemic lytic state the thrombolytic agent must enter the general circulation. When thrombolytic therapy is instituted systemically the lytic agent activates circulating plasminogen. Once all the plasminogen has been converted additional activity depends on further plasminogen production by the liver and activation of the plasminogen in the clot. Thus with a prolonged continuous infusion the activity of the drug depends more on the production of plasminogen by the liver than on the amount of drug administered[11].

Thrombolytic agents

All the thrombolytic agents currently in use or under development act directly or indirectly as plasminogen activators[13]. Streptokinase was discovered in 1933 when it was observed that a filtrate of group C β-haemolytic streptococci lysed a human plasma clot[14]. Urokinase initially isolated from human urine in 1946 is now obtained from tissue culture of human embryonic kidney cells[15]. Urokinase activates plasminogen directly and has a more predictable therapeutic response than streptokinase which forms an equimolar complex with plasminogen or plasmin and this complex activates the remaining plasminogen[16]. Streptokinase must neutralize any streptococcal antibodies present in the circulation before a lytic state can be achieved. Following the administration of streptokinase, antibodies are produced which preclude the use of streptokinase for 1 year. Urokinase is less antigenic and does not have this problem with antibodies. However, urokinase is almost 20 times as expensive as streptokinase for an equivalent therapeutic dose[17].

As both urokinase and streptokinase activate circulating plasminogen, thus depleting plasma plasminogen levels and leading to the degradation of fibrinogen and the other clotting factors, there is a growing interest in 'fibrin-specific' plasminogen activators[13]. Although these agents have a higher ratio of activity for fibrin-bound plasminogen they do activate plasma plasminogen and in therapeutic doses cause systemic fibrinogenolysis[13]. Tissue plasminogen activator is now being made in tissue culture by recombinant DNA techniques utilizing a mammalian cell line. Animal studies and laboratory tests have shown it to be an effective thrombolytic agent[18,19]. Tissue plasminogen activator forms a complex with fibrin and plasminogen. This complex specifically activates plasminogen in the presence of fibrin and should have little effect on circulating plasminogen. Therefore theoretically it should induce local thrombolysis without systemic fibrinolysis. However, studies have shown the same incidence of bleeding episodes among patients treated with tissue plasminogen activator and those treated with streptokinase after myocardial infarction[20]. Further clinical trials are in progress[21,22].

Investigators continue to attempt to improve the specificity and efficiency of streptokinase and urokinase The development of prourokinase[23] and fibrin-seeking urokinase[24] has recently been reported Prourokinase is an inactive proenzyme which is slowly activated in the presence of a fibrin clot Fibrin-seeking urokinase (urokinase coupled with a monoclonal antibody that is fibrin specific and does not cross-react with fibrinogen) has demonstrated a 100-fold increase in *in vitro* fibrinolysis when compared with unmodified urokinase[25]. Selective clot lysis can be achieved by acylating the streptokinase–plasminogen complex to form anisoylated plasminogen–streptokinase activator complex (APSAC). When the complex is bound to fibrin, deacylation occurs and fibrin-bound plasminogen is activated[3,25].

The 'fibrin-selective' agents have been used predominantly after myocardial infarction[13]. Evidence suggests that there is an inverse relationship between the degree of fibrin selectivity and the lytic state achieved[13]. After myocardial infarction, when thrombolytic agents are used in therapeutic doses, the lytic state is greatest with streptokinase and APSAC[20,26], is at an intermediate level with urokinase[27], and is more moderate with prourokinase and tissue plasminogen activator[20,28]. Although relative fibrin specificity is important in the development of a lytic state the plasma half-life of each agent also influences the outcome, with prourokinase and tissue plasminogen activator having a rapid turnover[28,29], streptokinase[30] and urokinase[31] having intermediate rates and APSAC having the slowest rate[32] Rethrombosis after reperfusion occurs in roughly inverse proportion to the length of plasma half-life with the lowest incidence following APSAC[26,32], urokinase[27], and streptokinase[33], and the highest following tissue plasminogen activator[33,34]. These findings, in patients after myocardial infarction, may have important implications for surgical practice.

Indications for fibrinolytic therapy

The major indications for fibrinolytic therapy are deep venous thrombosis, pulmonary embolism, occlusion of native arteries, occlusion of venous or prosthetic grafts, and thrombosis of renal dialysis sites (shunts, fistulae and interposition grafts). Anecdotal reports of successful management of thrombosed coeliac, superior mesenteric and renal arteries with regional fibrinolytic therapy exist[35-37]. However, visceral artery occlusion is not a common indication because of the inability of these organs to tolerate prolonged ischaemia.

Contraindications for fibrinolytic therapy

Fibrinolytic therapy is contraindicated for 10 days after surgical procedures and parturition and for 3 months after the insertion of a vascular graft. Other contraindications include a bleeding diathesis, blood dyscrasias, liver disease, recent cerebrovascular accident or gastrointestinal haemorrhage. Although thrombolytic agents have been successfully used intraoperatively[38,39] to lyse residual thrombus following thromboembolectomy, more information is required before this can be regarded as an indication. Meanwhile recent surgery remains an absolute contraindication.

Therapeutic regimens

There are three commonly used regimens for administering thrombolytic agents. The commonest method is the continuous infusion of a thrombolytic agent into either a peripheral or central vein. Streptokinase is administered in an initial dose of 250 000 units over the first hour and 100 000 units every hour for the duration of therapy. Urokinase is administered in an initial dose of 4400 units kg^{-1} over 30 min and 4400 units $kg^{-1} h^{-1}$ for the course of therapy Duration of therapy is determined by the clinical response and is usually 72–96 h.

The second regimen is the infusion of a low dose of the thrombolytic agent directly into the clotted vessel. This method was introduced in the hope of increasing the rate of fibrinolysis and decreasing the systemic lytic effects and other complications[40,41]. A catheter is placed with its tip at the site of the occlusion Streptokinase in a dose of 5000–10 000 units h^{-1} or urokinase in a dose of 20 000–40 000 units h^{-1} is infused. Treatment times vary from 12 to 72 h depending on the clinical response

A third regimen which uses streptokinase or urokinase in an intermittent dosage schedule has been called 'burst' therapy[42,43]. Using this regimen 250 000 units streptokinase or 4400 units kg^{-1} urokinase is infused during the first hour of therapy This is followed by 100 000 units h^{-1} streptokinase or 4400 units urkinase $kg^{-1} h^{-1}$, for 4 h. The infusion is then discontinued for 12 h to allow the liver to replenish the circulating plasminogen. After this, 100 000 units streptokinase or 4400 units kg^{-1} urokinase is given over a 1-h period twice daily for 4–6 days. The duration of therapy is dictated by the patient's response.

A fourth regimen significantly reduces mortality following myocardial infarction and may be potentially useful for evaluation in peripheral arterial and venous thrombosis. In this regimen a bolus of streptokinase ($1{\cdot}5 \times 10^6$ units) is infused over 1 h[13]

Monitoring during therapy

Before commencing therapy a partial thromboplastin time, prothrombin time, haematocrit, fibrinogen level and platelet count are usually obtained to screen for a coagulopathy. Laboratory monitoring does not accurately predict the likelihood of bleeding or of successful clot lysis[44] All patients should be carefully monitored but it has been shown that it is not necessary to confine them to the intensive care unit[42]. Determination of a partial thromboplastin time and fibrinogen levels 3 h after commencing therapy will indicate if a lytic state has been achieved. The therapeutic effect of thrombolytic therapy is most accurately determined by serial angiography or non-invasive methods[42].

Deep venous thrombosis

The therapeutic objectives of therapy in deep venous thrombosis are the promotion of thrombus resolution and the restoration of normal venous circulation in the affected veins thus relieving symptoms and preventing the post-phlebitic syndrome All goals of treatment may be achieved by using thrombolytic therapy[45]

It has been reported that only 15 per cent of patients with deep venous thrombosis are candidates for thrombolytic therapy[46] The majority of patients have a contraindication such as recent surgery. The size and location of the clot, the underlying risk factors for deep venous thrombosis and the particular fibrinolytic agent used do not seem to alter the outcome of therapy[47]. Patients with iliofemoral thrombosis and impending venous gangrene are particularly suitable and thrombi in veins draining the upper extremities have also been reported to respond favourably[48,49] However, in those patients suitable for thrombolytic therapy it is inappropriate to begin heparin therapy and then to change to thrombolytic agents after 2 or 3 days because the chance of successful lysis is decreased by 50 per cent[50]. Randomized studies comparing streptokinase and heparin in the treatment of deep vein thrombosis have shown that clot lysis was significantly more likely with streptokinase but there was also a higher incidence of haemorrhagic complications[51] with this agent.

Restoration of the venous system to normal is achieved in 90–95 per cent of patients if thrombolytic therapy is administered within 5–7 days of the onset of symptoms[52-54] Results are less favourable if thrombosis has been present for more than 5 days The venous system will return to normal in less than 50 per cent of these patients[50]. After 10 days of symptoms, only 10–15 per cent of patients receive benefit from thrombolytic therapy[45].

In long-term follow-up studies, 77 per cent of patients with popliteal, femoral, or iliofemoral thrombosis treated with anticoagulants alone remained symptomatic[55]. In other prospective studies comparing streptokinase and heparin therapy for similar indications, there were significantly fewer symptomatic patients in the streptokinase-treated groups[52,56,57]. Streptokinase is as effective as heparin in preventing pulmonary emboli[58]. Kakkar *et al.*[59] showed that normal venous valvular function was maintained for 6–12 months in 47 patients treated with streptokinase However, subsequent studies by the same authors showed the same degree of haemodynamic impairment over a 2-year period in two groups of patients, irrespective of whether they were treated with heparin or with streptokinase[60]. With regard to the ability of streptokinase therapy to prevent late post-thrombotic changes in the affected limb, the evidence is equally confusing. Arnesen *et al.*[52] suggest that streptokinase is effective in preventing late post-thrombotic changes while Kakkar and Lawrence[60] have produced evidence to the contrary.

Pulmonary embolus

Thrombolytic agents combined with heparin have been shown to be superior to heparin alone in the management of pulmonary embolus[58]. These patients had a more rapid improvement in abnormal perfusion lung scans and elevated pulmonary artery pressures than did patients who received heparin alone. The difference in physiological response was specially evident in patients with massive pulmonary embolism (more than two lobar arteries involved) and symptoms for less than 48 h and could be achieved equally well with streptokinase or urokinase. Similar effects have been demonstrated with tissue plasminogen activator[61,62]. Other studies have revealed that thrombolytic therapy achieved earlier lysis of the clot and a more rapid improvement in pulmonary haemodynamics[3,6,63,64]. In addition, thrombolytic agents may restore diffusion capacity and prevent pulmonary hypertension[3,6,64]

However, the evidence for a lasting advantage of thrombolytic therapy over heparin therapy alone is as yet inconclusive. In the Urokinase–Streptokinase Pulmonary Embolism Trial there was no difference in mortality rates between patients treated with heparin and those treated with thrombolytic agents[58] although in a subgroup in this study mortality was lower with urokinase therapy than after emergency pulmonary embolectomy. Percutaneous transvenous embolectomy with a suction device that allows withdrawal of thrombus from the main pulmonary arteries has not received widespread acceptance and there is insufficient information available to compare this modality with thrombolytic therapy[65]. In other randomized studies in patients with massive embolism and clinical shock, reperfusion was more successful after thrombolytic therapy[66,67]. Thus, unless contraindicated by a lifethreatening risk of haemorrhage, thrombolytic therapy appears to be the treatment of choice for pulmonary embolism with acute pulmonary hypertension, shock responding to medical treatment, and complete perfusion defects involving one or more lobes[3].

Evidence from animal experiments suggests that clot is more rapidly lysed when fibrinolytic agents are infused directly into the thrombus[7]. The next most rapid lysis occurred with infusion into the pulmonary artery while peripheral venous infusion was least efficient[68]. These animal studies are corroborated by recent clinical studies[63].

Peripheral vascular disease

Thrombolytic therapy has been used in a variety of arterial occlusive processes including upper and lower limb ischaemia, occlusion of bypass grafts and thrombosis after percutaneous transluminal angioplasty[69,70] Selection of patients for thrombolytic therapy depends on a number of factors including the general condition of the patient, the severity and duration of the ischaemia and the underlying cause[71]

As a rule, thrombolytic therapy should be considered when the morbidity and mortality associated with the surgical alternative are higher than the anticipated incidence of serious haemorrhagic complications associated with therapy Such high risk patients include patients after myocardial infarction, those with lower limb ischaemia, thrombosis of a popliteal aneurysm, emboli to distal muscular arteries or surgically inaccessible vessels, and those with diffuse thrombosis[71,72]. As surgical results are generally poor and the amputation rate is high with occlusion of the popliteal or tibial vessels, even good-risk patients may be candidates for thrombolytic therapy. Patients with the blue toe syndrome (occlusion of the digital arteries) and trash foot (distal embolization following arterial surgery) may also be candidates for thrombolytic therapy[50]. Thrombolytic agents are contraindicated if the acute ischaemia has resulted in a neurological deficit, i.e. numbness and/or paraesthesia. It is also inappropriate in patients who cannot tolerate the ischaemia during the infusion period. Although it is desirable to differentiate between embolus and thrombosis, this is frequently impossible. Emboli can be lysed in up to 80 per cent of cases while thrombolytic occlusions have been reported to be lysed in 50–60 per cent of cases[41,73,74]. Intraoperative infusion of lytic agents has been used successfully after thromboembolectomy in patients where arteriography demonstrated residual thrombus distal to the popliteal artery. There were no complications related to the infusions[38,39].

The incidence of successful thrombolysis in acute arterial and bypass graft occlusion is very variable (30–90 per cent (*Table 1*)). Occluded arteries and bypass grafts were initially treated by systemic thrombolytic administration but the increased efficacy of local therapy has been recognized, particularly for bypass grafts[25,40–44]. It has been shown that the fibrinolytic effect is magnified if the agent is injected directly into the clotted graft Improved results are also reported if a passageway is made by means of a catheter or guidewire, although there may be a higher incidence of vessel dissection and peripheral embolism[86,87]. The greatest potential benefit from thrombolytic treatment is in patients with occluded autogenous vein grafts[71]. Restoration of flow in an occluded graft permits complete angiographic evaluation of the graft and may identify the cause of the graft failure, which can then be corrected. Indeed, two-thirds of all patients with acute arterial or bypass graft occlusions that respond to thrombolytic therapy require further therapeutic intervention[73,75,88].

Thrombosed catheters, dialysis shunts and arteriovenous fistulae

Central venous catheters can be cleared by injecting a small quantity of concentrated streptokinase solution (250 000 units in 2 ml) to fill the lumen. After 1 h the catheter is aspirated and flushed[3]. Fibrinolytic agents are more effective in clearing dialysis shunts than arteriovenous fistulae[89,90]. However, the risk of haemorrhagic complications in this group is high[91].

Adjunctive anticoagulation

There is a higher incidence of haemorrhagic complications where thrombolytic agents and anticoagulants are administered simultaneously[44]. However, there is debate about whether concomitant anticoagulation with heparin should be used during the local infusion of fibrinolytic agents for arterial occlusion. Some authors believe that anticoagulation causes a reduction in rethrombosis around the catheter as thrombolysis progresses more distally[1,77], while others believe it is an unnecessary hazard[70]. The low flow, low pressure characteristics of the venous system predispose to rethrombosis following thrombolytic therapy if anticoagulants are not used[25]. Heparin may be administered for 1 week followed by an oral anticoagulant (coumarin) for 3 months[16]. 'Burst' therapy has been shown to decrease hospital time and to be more cost-effective[42]. Administering coumarin the evening before the last dose of streptokinase markedly reduces the time required to anticoagulate the patient[42] adequately.

Discussion

It is unlikely that there will ever be an ideal thrombolytic agent, i e one that is non-antigenic, inexpensive, selectively dissolves thrombus and that acts quickly, completely and without complications. It is probable that there will always be an increased risk of bleeding because it is difficult to conceive of any agent dissolving the fibrin of an intravascular clot while not dissolving the fibrin of a haemostatic plug. However, the thrombolytic agents currently used in surgical practice or following myocardial infarction (streptokinase, urokinase, tissue plasminogen activator, prourokinase and APSAC) can be improved. Fibrin specificity can be improved by complexing any of these agents with a monoclonal antifibrin antibody[92]. A disadvantage of streptokinase and APSAC is their antigenicity, which limits their use in retreatment as well as exposing

patients to an increased risk of allergic reactions. Streptokinase and APSAC have been reported to lose their antigenicity following treatment with polyethylene glycol[93] The short half-life of most of these agents (tissue plasminogen activator, 5 min, prourokinase, 7 min; urokinase, 16 min; streptokinase, 23 min) usually requires their administration in large amounts over a long period. Techniques for prolonging the half-lives of these agents are being developed[94] This may be achieved by acylation of the active enzyme centre as in APSAC or by pharmacologically altering the mechanisms for their inactivation[95]. The potential for combining thrombolytic agents needs to be explored Tissue plasminogen activator and urokinase have been shown to act synergistically, significantly reducing the amount of each needed to effect clot lysis[96]. Recombinant DNA techniques which can create unique molecules with altered domains and susceptibility to plasmin clearance will be used to create new thrombolytic agents. The cost of thrombolytic therapy will be an important consideration with regard to both the initial purchase price and the cost of caring for patients with thrombotic disease[14] Although expensive, thrombolytic therapy will probably become more cost-effective by decreasing the length of hospital stay and reducing the need for emergency surgery

For the moment thrombolytic therapy affords the possibility of removing intravascular thrombi before irreversible tissue damage or organ failure occurs In contrast anticoagulant therapy merely prevents extension of the thrombotic process The lack of enthusiasm for thrombolytic therapy is attributed to two factors[71]: firstly, the perceived high risk of serious haemorrhage and other systemic complications and, secondly, the paucity of controlled randomized clinical trials documenting the efficacy of treatment.

It is difficult to determine the incidence of significant haemorrhagic complications because there are no standard criteria for assessing these complications. The incidence in reported series varies from zero to 60 per cent (*Table 1*). In the Urokinase–Streptokinase Pulmonary Embolism Trial, the incidence of bleeding requiring transfusion of 1 or more units of blood varied from 13 to 18 per cent[58]. The incidence of systemic haemorrhagic complications varies with the method of thrombolytic administration. It is highest with intravenous use and is reduced by local catheter administration[1,71]. However, with the latter method, haemorrhage around the catheter site is significant[69], occurring in 20 per cent of patients in one series[97]. In addition, even with local infusion a systemic lytic state develops within 12–24 h and major or minor haemorrhagic complications occur in 15–30 per cent of patients[25]. The duration of therapy directly influences the incidence of haemorrhagic complications[44]. Partial thrombolysis should be apparent within 24 h and continuing therapy without evidence of beneficial effect beyond 48–72 h seldom yields a more favourable outcome[1]. With prosthetic grafts (Dacron® (E I. du Pont de Nemours and Company) and less commonly polytetrafluoroethylene) the fibrin in the interstices may be digested, resulting in significant bleeding[98]. The choice of agent may also be important. Urokinase and tissue plasminogen activator have been reported to be associated with a lower incidence of haemorrhage than has streptokinase[1,19,85]. Tissue plasminogen activator has been reported to lyse pulmonary emboli more effectively than urokinase[62] However, there is as yet no evidence from large randomized studies to support these reports. Cerebrovascular haemorrhage, the most dreaded of all complications, has been reported in 2·2 per cent of cases[99].

Comparison of success rates in various series (*Table 1*) is difficult owing to the many factors that may influence the outcome, e.g the thrombolytic agent chosen, the technique of administration, the dosage regimen used and the selection of patients. Some general observations can be made. Acute occlusions respond better than chronic occlusions and short occlusions better than longer segments. Urokinase may be more effective than streptokinase. With the use of local low dose therapy, bypass graft may now respond as rapidly as native vessels. In selecting patients for fibrinolytic therapy, careful clinical assessment and consideration of clinical alternatives are necessary to minimize the risks and maximize the benefits.

In conclusion, fibrinolytic therapy has a definite role in surgical practice. This role may be expanded by the greater specificity of tissue plasminogen activator and by agents such as prourokinase, fibrin-seeking urokinase and APSAC which are currently being investigated. All of these agents can be improved, and recombinant DNA technology will be used to develop new agents. Newer non-invasive techniques provide the opportunity to study their effects during therapy and subsequently over a period of time.

Journal of the
Royal College of Surgeons
of Edinburgh

Published on behalf of The Royal College of Surgeons of Edinburgh

Chairman: Sir James Fraser BT ChM FRCS Ed
Editor: Alfred Cuschieri MD ChM FRCS(Ed & Eng)

The *Journal of the Royal College of Surgeons of Edinburgh* was established in 1955 and since that time the journal has grown and it is now a widely read journal in the field of surgery. It provides a forum for the publication of a broad range of original papers drawn from fellows of the Royal College and other surgeons world wide which will interest not only the practising surgeon but also those in allied fields.

Complementing the main articles are three sections: **Reviews** – containing invited review articles, **Clinical Notes** – with brief accounts based on surgeons' experience and, **Surgeons Workshop** – containing short articles on innovations in surgical techniques and devices. The journal also carries reports of major scientific meetings, book reviews and correspondence.

The journal has been adopted by the Association of Academic Departments of Surgery in Europe. Abstracts of papers presented at the meetings of the Association are published in the journal.

Topics covered by the *Journal of the Royal College of Surgeons of Edinburgh:*

- **Colorectal and anal surgery**
- **Gastrointestinal surgery**
- **Neurosurgery**
- **Oncology**
- **Ophthalmology**
- **Orthopaedics**
- **Otolaryngology**
- **Paediatric surgery**
- **Plastic and reconstructive surgery**
- **Thoracic surgery**
- **Transplantation**
- **Trauma**
- **Urology**
- **Vascular**

Journal of the Royal College of Surgeons of Edinburgh is published bi-monthly ISSN 0035 8835

Fine Needle Aspiration of the Breast

Yolanda C Oertel MD
Professor of Pathology, The George Washington University, School of Medicine, Washington DC, USA.

- ★ **Clearly and concisely written with extensive illustrations including many in colour**
- ★ **Cover all the aspects of the technique from performance to evaluation**
- ★ **Essential reading for surgical pathologists involved in performing aspirations**

Fine needle aspiration is a valuable diagnostic tool that is gaining increased acceptance in the United States. It helps clinicians and surgeons arrive at a more accurate diagnosis in a timely and economical fashion and enhances their ability to manage patients more effectively. This monograph is the product of nine years' experience in which about 10,000 aspirates were interpreted or performed. It covers all aspects of the technique, from performance of the aspiration and processing the specimen, to the evaluation of the information obtained from the procedure. As this experience has shown that results are superior when the aspiration is performed by the pathologist, the emphasis throughout is on the technical aspects of the procedure. The text is extremely well illustrated to facilitate evaluation and differentiation of findings. The result is a clearly written, practical guide to fine needle aspiration of the breast.

Contents

Introduction • Advantages and disadvantages of needle aspiration • Questions asked more frequently • Fine needle aspiration technique • How to succeed at fine needle aspiration • Usual findings in the aspirates • Occasional findings in the aspirates • Benign lesions • Atypical ductal hyperplasia • General diagnostic criteria of malignancy • Adenocarcinomas • Malignant nonepithelial neoplasms • Metastic tumors in the breast • Thoracic wall recurrences and axillary masses • Pitfalls • Fine needle aspiration of nonpalpable breast lesions • Additional diagnostic information • Statistical summary • References • Index

Mr P W Leopold

Two hundred and eighty patients underwent B-mode mapping (B-map) of their saphenous vein over a period of 3 years (1984–1987) before lower limb revascularization. B-map deemed that 229 veins were suitable for bypass, 26 were questionable and 25 were unsuitable. A successful bypass was achieved in 97·8 per cent of the suitable group (all in situ*), 85 per cent of the questionable group (*in situ *and composite vein), and 80 per cent of the unsuitable group (composite vein). At a minimum follow-up period of 1 year the overall patency rate was 95·0 per cent with a revision rate of 15·8 per cent. There was no correlation between revision rate and vein complexity or calf vein diameter. Calf vein diameter >2·5 mm was correlated with a successful bypass (*$P<0{\cdot}001$*). It is concluded that B-map is the investigation of choice for saphenous vein assessment before infrainguinal bypass surgery.*

Keywords: Ultrasound, B-mode, infrainguinal bypass, saphenous vein

Autogenous saphenous vein, whether *in situ*, reversed, or composite, has been proved to be the best available conduit for infrainguinal arterial reconstruction[1–3]. Many authors now feel that, where possible, the *in situ* saphenous vein bypass offers the best surgical option[4].

The *in situ* bypass may be performed using techniques of either partial or complete saphenous vein exposure. We have preferred the technique of partial vein exposure to reduce skin flap necrosis, increase speed of surgery, and reduce operative time[5]. Under these circumstances we have found it essential to have a full and detailed knowledge of the saphenous venous anatomy particularly in the unexposed thigh section of the saphenous vein. Pre-bypass venography has been used by ourselves and others to determine saphenous vein anatomy[6,7]. Some authors have warned against the use of saphenous veins other than single systems for vein bypass surgery. This approach would lead to a vein utilization rate as low as 60 per cent. Our experience with pre-bypass venography was associated with a vein utilization rate of 95 per cent. With the development of B-mode imaging, a further technique became available to preoperatively assess the greater saphenous vein. Our initial trial of preoperative venography against B-mode mapping (B-map) in 50 consecutive patients was favourable, suggesting the use of B-map as an independent technique with certain guidelines[9]. Since then others have published their initial experience with superficial venous imaging[10]

The aim of this study was to determine: firstly, whether B-map adequately assessed the saphenous vein, achieving similar vein utilization rates as venography; secondly, whether vein diameter and complexity of the venous system affected the outcome; and lastly, whether there was any advantage of B-map over venography in terms of anatomical three-dimensional detail and the facilitation of better infrainguinal bypass technique, avoiding the complications previously ascribed to partial vein exposure.

Patients and methods

Two hundred and eighty consecutive patients underwent B-map of their saphenous veins between 1984 and 1987. All these patients presented with limb-threatening ischaemia[11] The mean age was 67·5 years with a male preponderance (65 per cent), 48 per cent of patients were diabetic and 67 per cent were smokers

B-mode mapping (B-map)

All patients were examined in a position of 20° reverse Trendelenberg tilt as previously described. Starting at the knee joint the saphenous vein was visualized using a Diasonics DRF 400 Duplex scanner (Sonatron Ltd , Bedford, UK), utilizing a 10 MHz imager The cross-sectional scan was used to measure the venous diameter, and the vein path along the limb was marked from the longitudinal scan The main trunk was followed from the knee proximally and distally, marking (1) the path, (2) the diameter, (3) the cutaneous and deep branches and (4) double/triple/more complex systems. A full-length map of the saphenous system including, if necessary, the short saphenous system was marked on the leg The internal diameter of the vein was recorded in the proximal and distal thigh regions and at the knee and ankle levels. A re-examination was performed in the standing position, if the patient's condition allowed, to ensure adequate venous filling Patients with complex systems and inadequate B-map examinations underwent venography, at the discretion of the clinician

Results

Two hundred and twenty-nine veins were deemed suitable for bypass, 26 were questionable (< 2·5 mm at the calf but complete and patent), and 25 were unsuitable (incomplete, previously excised, damaged or diseased)

A successful bypass was achieved in 97 8 per cent of the suitable vein group (all *in situ*), 85 per cent of the questionable group (*in situ* plus composite vein) and 80 per cent of the unsuitable group (composite vein, *Figure 1*). In 23 patients (out of the 51 questionable or unsuitable) branches of the long or short saphenous were used for composite vein grafting or short saphenous *in situ* bypass (*Table 1*); 34 per cent of the bypasses were to the popliteal level and 66 per cent were infrapopliteal.

Patients were followed up at 1 month and then at 3-monthly intervals. This included a symptomatic enquiry, clinical examination and vascular laboratory studies, including pulse volume recording and Duplex scanning of the bypass.

There was a minimum follow-up period of 1 year for all bypasses resulting in a secondary patency rate of 95 per cent[11]. The revision rate was 15·8 per cent (42/266) An analysis of vein complexity in the thigh (double, triple or branching systems), and revision rate showed no statistical difference (*Table 2*). Also an analysis of calf vein diameter and revision rate showed no

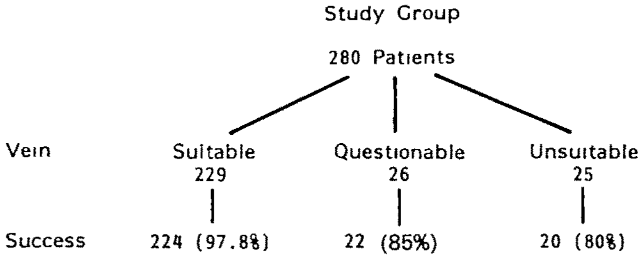

Figure 1 *The result of the B-map studies in 280 patients in relationship to the outcome of the surgical procedure*

0007-1323/89/030305-03$3.00 © 1989 Butterworth & Co (Publishers) Ltd

Table 1 *Alternative veins (composite bypasses) used in 23 patients*

Femoropopliteal	9
Femorodistal	7
Vein patch	4
Short saphenous *in situ*	3

Table 2 *Vein complexity and revisions*

	Revisions	Non-revisions	Total
Complex	17	99	116
Non-complex	25	125	150
Total	42	224	266

$\chi^2 = 0{\cdot}19$, n.s

Table 3 *B-mode vein diameter*

Position	Mean ± s.d. (mm)
Proximal thigh	4·360 ± 1 050
Distal thigh	3 660 ± 0 900
Knee	3·383 ± 0·925
Calf	2·834 ± 0·731*
Ankle	3·040 ± 0 756*

* Significant difference $t = 2{\cdot}482$, $P < 0{\cdot}02$

statistical difference. (Revised bypass calf diameter in millimetres, 2·86 ± 0 71, $n = 42$; non-revised 2·76 ± 0 21, $n = 224$ (mean ± s.d.); *t* test n.s.) However, comparing the calf vein diameter above and below 2·5 mm showed a significant difference in the feasibility of a successful bypass (<2 5 mm, 19/29; >2·5 mm, 224/229; $\chi^2 = 49{\cdot}04$, $P < 0{\cdot}001$).

It is interesting to note that the saphenous vein diameter decreased from groin to calf (*Table 3*), but increased significantly at the ankle (mean diameter calf 2 834 ± 0·731 mm, ankle 3·040 ± 0 756 mm; *t* test $t = 2{\cdot}482$, $P < 0{\cdot}02$).

Discussion

During *in situ* saphenous vein bypass using a technique of partial vein exposure, the complexity of the saphenous vein within the unexposed thigh section is all important. Double or triple systems lying in deep and/or superficial tissue planes occur in up to 40 per cent[6,9].

Within this series the overall detection rate for complex systems was 42 per cent, much in line with our previous findings, while the 1-year bypass patency rates and revision rates remained essentially unchanged from our previous series using venography and other published series[1,4,6] These findings are even more encouraging when we reflect on the rate of back-up venography during this period. In our initial comparison of B-map and venography we felt that any double or more complex system or inadequate B-map should be backed up with either preoperative or intraoperative venography. Within this series the back-up venography rate was less than 10 per cent. This meant that at least 30 per cent of patients went to surgery with potentially complex saphenous systems without back-up venography with no apparent deleterious effect.

Assessment of vein size using B-map and venography has previously been assessed and found to be of variable accuracy[6,7,9]. Although calf vein diameter did not appear to affect the revision rate, a vein diameter of 2·5 mm seems critical in determining the feasibility of bypass. We have attempted to select the most suitable vein based on vein size at the calf, vein continuity and patency on B-map. Patients in the suitable vein group had a higher incidence of successful bypass surgery with a vein utilization rate of 97·8 per cent. A small group of patients were selected ($n = 26$) where the vein was deemed questionable. Of these, 19 underwent successfully *in situ* bypass who, on previous criteria, would have been rejected. A further three patients underwent a composite vein bypass. A final group of 25 patients had unsuitable veins; 80 per cent of these patients underwent composite vein bypass, arterial patching, or short saphenous *in situ* bypass as previously described[12]

Taylor *et al.*[2] have used the composite vein bypass as an addition to their surgical armamentarium to maintain high vein utilization rates in their reverse vein bypass series with excellent results. Despite the ability of B-map to select more favourable saphenous veins, it is not sufficiently good to allow exclusion of patients from surgery on the basis of an inadequate vein on B-map This is further emphasized by the high success rate for composite vein bypass within ours and other series[3]. One other contributing factor to the high operability and limb salvage rate in this group of patients may have been the wider application of B-map to look at the short saphenous and other superficial venous systems in an attempt to search for suitable 'bypass material'.

A more detailed assessment of vein size within the lower leg has raised an important point. that of the larger vein size at the ankle than at the mid calf level. This could be particularly important when deciding on the level of distal anastomoses. For example, if an equally good artery existed at the two sites for anastamosis, then the more distal site around the ankle, as opposed to the mid calf, might be advantageous. It is interesting that distal anastomotic vein size has been shown to correlate with bypass patency in some series[13] However, in these series no mention was made of the incidence of narrower calibre veins 'upstream' from the distal anastomosis.

There may be a further potential advantage of the larger vein size at the ankle and the ability to detect it for surgeons who perform reversed vein bypasses; namely, it has been said that one of the limiting factors to the performance of reverse vein bypass is the size of the vein to be used for the proximal anastomosis with a figure of 4 mm being suggested as the lower limit[4]. Utilizing B-map it should now be possible to select the section of vein for reversal so that optimal vein diameters exist at both extremities

From this study we have shown that B-map has allowed maintenance of equally high levels of bypass success with no increase in the bypass revision or failure rate. It must be concluded that this technique is a sufficiently good determinant of complexity of the saphenous vein to allow the maintenance of standards for arterialized *in situ* bypass surgery using a technique of partial exposure.

Finally, B-map has allowed us to look for veins from any of the superficial venous systems for their suitability as bypass conduits. In conclusion, where available, B-map should be the first line of investigation of choice to image and map the superficial veins before vein bypass surgery.

Crossover femoral grafting to allow subsequent donor limb angioplasty

A. R. Baker and W. W. Barrie

Leicester General Hospital, Gwendolen Road, Leicester LE5 4PW, UK
Correspondence to: Mr W. W. Barrie

The femorofemoral crossover graft, in its present form in which a relatively short prosthetic graft is routed subcutaneously between the two common femoral arteries, was proposed by Vetto in 1962[1]. This procedure rapidly gained popularity in the treatment of high-risk patients with peripheral ischaemia due to unilateral iliac occlusive disease. Mortality and morbidity rates were low and long-term patency rates were good. As a result the indications have been broadened[2] and it has been recommended as the procedure of choice for all patients with unilateral iliac disease[3,4] In some series, up to half the patients with proximal disease coming to surgery have been treated successfully by crossover grafting[5].

Atheroma is, however, a generalized disease and aortoiliac lesions are often symmetrical[6]. With wider indications for the femorofemoral crossover graft, it is increasingly important to ensure the adequacy of the donor limb. This may be achieved by noninvasive studies[7,8], although our preference is for intra-arterial pressure measurement with papaverine testing[9]. If haemodynamically significant donor limb disease is revealed it may be treated by transluminal angioplasty at the time of operation[10,11].

With proper case selection, although there may be a deterioration of donor limb haemodynamics following operation, this should not manifest itself clinically[8,12]. Graft failure usually results from progression of recipient limb distal disease, however in 2·5–4 per cent of femorofemoral crossover grafts it follows progression in donor limb proximal disease. As the indications broaden to include patients with greater life expectancy, this is likely to become a more common problem. Failure of the standard common femoral to common femoral crossover graft necessitates further surgery, either by aortofemoral grafting with its increased mortality and morbidity rates or by axillofemoral grafting which is associated with reduced long-term patency. Progression of donor limb atheroma is very difficult to treat by percutaneous transluminal angioplasty as both groins are scarred and both common femoral arteries are sites of graft anastomoses.

We have recently been using the external iliac as the donor artery for the crossover graft (*Figure 1*). Exposure is retroperitoneal, through a very short incision placed a little above the inguinal canal The graft is tunnelled retroperitoneally along the upper border of the pubis and brought under the opposite inguinal ligament The anastomosis to the recipient artery may then incorporate a profundaplasty. We recommend this method as the donor limb common femoral artery remains intact and can be used as a route for subsequent angioplasty if disease develops in this aortoiliac segment. The undisturbed common femoral artery may also be used more easily for subsequent femoropopliteal bypass

Major amputation in a defined population: incidence, mortality and results of treatment

Medical records of all patients, from a defined population of 88 000 inhabitants, who underwent major lower limb amputation during 1980–82 were retrospectively scrutinized. The records showed 131 amputations were performed in 106 patients at the district hospital and 22 amputations on 17 patients at the local university hospital, referral centre, altogether 57 men and 66 women. This gave an amputation incidence of 46 per 10^5 inhabitants per year. Of the amputees 47 per cent were older than 80 years. Only two patients underwent reconstructive vascular surgery (at the university hospital) before surgery. Final amputation level was above-knee in 61 per cent of the patients treated at the district hospital. Mortality rates at 30 days and 2 years after the amputation were 23 and 56 per cent, respectively, and the age-corrected survival after 2 years was 55 per cent. For patients who came from and eventually returned to their own homes the mean hospital stay amounted to 184 days (postoperative deaths excluded). After amputation 26 patients were trained to wear a prosthesis and 16 of these used the prosthesis 2 years after amputation. The present study underlines the need for prospective and parallel studies of vascular surgery and amputation as well as analyses of the risk factors involved in lower limb ischaemia in defined populations.

Keywords: Lower limb ischaemia, amputation incidence, epidemiology

**Department of Geriatric and Long Term Medicine, Motala Hospital, S-59185 Motala, Sweden*

Correspondence to. Dr E. Nilsson

The aim of the present report is to analyse the incidence and postoperative mortality of amputation together with the hospital stay and rehabilitation of amputees treated at a district hospital (Motala Hospital) which had neither a specialized vascular surgery service nor an orthopaedic surgery service available during the study period.

Patients and methods

The medical records until the end of 1985 of all patients from the catchment area of Motala Hospital who had had major lower limb amputations at Motala Hospital or its referral centre, the University Hospital of Linkoping, between 1980 and 1982 were reviewed Below-knee amputation was performed with a long posterior musculocutaneous flap and the wound was covered by a plaster of Paris dressing postoperatively After amputation and appropriate aftercare the patients were transferred from the surgical department to the department of Geriatric and Long Term Medicine at Motala Hospital for rehabilitation in collaboration with the orthopaedic unit at the University Hospital of Linkoping

Figures used to calculate the incidence of amputation for the catchment area of Motala Hospital (88 000 inhabitants) included patients from that area amputated at the University Hospital of Linköping, whereas all other data are based only on patients treated at the Motala Hospital Age-corrected survival was calculated according to the life table method

Results

Patients and amputation incidence

From 1 January 1980 to 31 December 1982, 106 patients, 48 men and 58 women, underwent 131 lower limb amputations at Motala Hospital. The mean age of the patients was 79 years (range 28–95 years). For diabetics the corresponding figures were 76 years (28–95 years) and for patients without diabetes 80 years (61–94 years). During the same time 22 lower limb amputations (13 below-knee and nine above-knee) were performed at the University Hospital of Linköping on 17 patients from the catchment area of Motala Hospital. The mean age of these 17 patients was 72 years (range 35–90 years) The incidence of amputation in the area was thus 46 per 100 000 inhabitants per year. The numbers of amputees and inhabitants in each age decade are given in *Table 1*. In these calculations two patients amputated because of trauma were excluded.

Table 2 illustrates the disease states of patients treated at the surgical clinic in Motala for lower limb ischaemia at the time of the study. As regards those patients with diabetes, three were

Table 4 *Mode of living and mortality of patients amputated in Motala hospital in the 3 years 1980–82*

Where patients lived (*n* = 106)	Before operation	After operation	
		6 months	2 years
Own home	43	26	25
Institution	63	39	22
Dead	—	41	59
Total	106	106	106

prescribed diet only, 18 had oral therapy and 27 were on insulin. Nineteen patients had bilateral lower limb ischaema, and nine had already undergone amputation of one leg. The duration of symptoms due to the disease resulting in amputation is shown in *Table 3*. In 16 cases symptoms ultimately leading to amputation started abruptly whereas three patients had had a few days illness before amputation. In 97 patients, half of whom were diabetics, amputation was preceded by a slowly progressing arterial insufficiency.

Forty-three patients (41 per cent) lived at home before being admitted with lower limb ischaemia and 63 (59 per cent) came from hospital wards or from institutions outside the hospital (*Table 4*).

Preoperative investigations

Angiography was performed on two patients. In nine cases Doppler measurements were made preoperatively, though no records of ankle pressures were found in the notes. For all other patients the indication for amputation was based on clinical examination alone.

Vascular surgery

Reconstructive vascular surgery was not performed on any of the patients who underwent amputation in Motala Hospital. During the period studied 20 patients underwent 23 embolectomies and eight of these patients (40 per cent) were amputated. Of the 17 amputees treated at the University Hospital of Linköping two had undergone reconstructive vascular surgery and one an embolectomy before amputation.

Level of amputation

Of 131 amputations 76 (58 per cent) were performed above the knee and 55 (42 per cent) below the knee. Delayed stump healing occurred in 21 patients (38 per cent) with below-knee amputation and in six patients (8 per cent) with above-knee amputation, necessitating reamputation in eight patients (15 per cent) and four patients (5 per cent) respectively, see *Table 5*.

Hospital stay

The mean stay at the surgical clinic for patients treated in Motala, postoperative deaths excluded, was 15 days For patients who came from and eventually returned to their own home the stay at the surgical clinic was 24 days and at the Department of Long Term Medicine 160 days

Mortality and rehabilitation

Mortality rate within 30 days of amputation was 23 per cent, with the highest rate (29 per cent) occurring among above-knee amputees. Of all patients, 39 per cent and 56 per cent were dead within 6 months and 2 years of amputation, respectively. For those patients who, before surgery, lived at home the corresponding figures were 37 per cent and 44 per cent The age-corrected survival figure after 2 years was 55 per cent Six months after surgery 60 per cent of patients who had initially lived at home had returned home. The mode of living and number of deaths in all patients are shown as functions of time after amputation in *Table 4*.

Of the 106 patients 26 (25 per cent) received a prosthesis, four above-knee amputees and 22 below-knee amputees. Of 43 patients who came from their own homes 19 (44 per cent) were supplied with a prosthesis compared with seven out of 63 (11 per cent) other patients Two years after amputation 16 of the 26 patients (62 per cent) trained to wear a prosthesis continued to use it in daily life.

Discussion

Amputation in populations of increasing age

Previous Swedish studies have demonstrated an increasing incidence of amputation since the beginning of this century[1–3], and the same tendency seems to prevail in the UK[4]. A population-based Danish study, however, showed a stable incidence during the 1960s[5]. Over the past 10 years amputation rates for the three largest cities of Sweden have been published; these varied from 21 to 40 amputations per 100 000 inhabitants per year[3,6,7]. In one previous study[3] 38 per cent of all amputations occurred among the 3 per cent of inhabitants who were older than 80 years compared with 46 per cent in the present report. It is appropriate, therefore, to consider the age shift which has taken place in the Swedish population over the past few decades. Within a very small overall increase in population (from 7 5 to 8·3 million) the proportion of people older than 80 years increased from 1 9 per cent in 1960 to 3·2 per cent in 1980. A similar trend, although more pronounced, took place in the defined population of the present study. Thus, in 1960 there were 1100 inhabitants older than 80 years and, in 1980 this figure was 3105—almost a threefold increase. It is, therefore, not surprising that the mean age of our patients is higher than in any previous Swedish report on amputees. Liedberg[3] found, however, that such an age shift within the population explained only part of the increase in amputations, and the same conclusion was reached in a study from the Oxford (UK) area[4]

From the present retrospective analysis no quantitative conclusion can be made concerning the most important risk factor for lower limb ischaemia—smoking habits The percentage of medically treated diabetics (45 per cent) among our patients is of the same order as in previous studies[3,7]. Only two of the 123 patients from the defined population studied had undergone reconstructive vascular surgery (in Linkoping) This is a lower figure than usually reported among amputees[3,4,8] and certainly suggests underusage of vascular surgery. (Recently, both vascular surgery and orthopaedic surgery have been introduced at our hospital.)

In contrast to previous reports, the amputation level among our patients was mostly proximal with only 39 per cent finally having below-knee amputations. Differences in amputation

Table 5 *Amputation level and complications in 131 amputations*

	Initial	Reamputation	Final level	Mortality*
Below-knee	55/119 (46)	8	47/119 (39)	8/55 (15)
Above-knee	64/119 (54)	4	72/119 (61)	22/76 (29)
Total		12		30/131 (23)

There were 119 primary amputations and 12 reamputations Values in parentheses are percentages *Within 30 days postoperatively level between defined populations may be due to differences in both treatment and age composition of the populations. Below-knee amputation in more than 70 per cent of amputees has been seen in some recent studies[3,8] The importance of orthopaedic knowledge covering both amputation surgery and rehabilitation is emphasized in several recent reports[3,6,7]. Relatively few (25 per cent) of our patients were trained to walk with a prosthesis[9], but 62 per cent of these amputees continued to use their prosthesis 2 years later.

In the present study, hospital stay at the surgical clinic was short (15 days). On the other hand, a long time was spent at the Department of Geriatric and Long Term Medicine. Even for those patients who came from, and eventually returned to, their own homes it amounted to 160 days. The age-corrected survival of our patients 2 years after amputation was 55 per cent which is in accordance with previous data from unselected populations[1,5,10]. Hansson[1] concluded that the mortality rate following amputation was four times greater than expected.

Preventive measures and the need for prospective studies

It has been indicated that treatment of diabetes and heart disorders are of great importance in lowering the incidence of amputation[10] Preventive medicine in this field should also include improvement of the patients' smoking habits, and early treatment of dysvascular foot lesions[11].

Vascular surgery is rapidly expanding in Scandinavia[12] but its role in prevention of major amputation is far from settled. There is a great need for prospective and parallel studies of both vascular and amputation surgery in defined populations. In such reports the number of vascular procedures and amputations as well as crude and age-corrected survival figures are necessary to allow meaningful comparisons. It should also be pointed out that in many respects limb salvage is a better end point than graft patency in the evaluation of vascular surgery[13].

Effect of shoulder immobilization on wound seroma and shoulder dysfunction following modified radical mastectomy: a randomized prospective clinical trial

I. Dawson, L. Stam, J. M. Heslinga and H. L. Kalsbeek

Department of Surgery, Bronovo Hospital, PO Box 96900, 2509 JH The Hague, The Netherlands
Correspondence to: Mr I Dawson

Wound seroma and shoulder dysfunction are the most frequent complications of a mastectomy[1,2]. To prevent the development of a frozen shoulder it seems justifiable to recommend postoperative exercises. However, early shoulder exercises may have a deleterious effect on wound healing and seroma formation.

The purpose of this study was to determine the effect of temporary shoulder immobilization on wound seroma and shoulder dysfunction following modified radical mastectomy.

Patients and methods

From March 1984 to October 1986, 100 women who underwent a modified radical mastectomy were randomized into two groups. The exercise group ($n = 51$) started to exercise on the first postoperative day. In the immobilized group ($n = 49$) the ipsilateral arm was immobilized in a sling for 5 days; then the same shoulder exercises were started. The two groups were comparable (*Table 1*).

On the fifth postoperative day, the suction drain (Redon* 14 Fr) was removed and the drainage volume recorded. Subsequently the wound was inspected daily. In the event of a seroma, aspiration followed until resolution.

To assess shoulder function, abduction and anteflexion were measured. All measurements were performed by the same individual. The corrected χ^2 test and Student's two-tailed t test were used for statistical analysis.

Table 1 *Comparison of related factors for the two trial groups*

Characteristics	Exercise group ($n = 51$)	Immobilized group ($n = 49$)
Physical factors		
Age (years)	64 ± 12	65 ± 14
Quetelet index (kg/m)^2	24 ± 4	24 ± 5
Shoulder function:		
Anteflexion (°)	154 ± 10	152 ± 10
Abduction (°)	152 ± 10	149 ± 11
Technical factors		
Staff surgeon: resident	26:25	24:25
Length of operation (min)	75 ± 15	73 ± 17
Tumour factors		
Tumour size (mm)	24 ± 13	25 ± 15
Involved lymph nodes (n)	2 ± 3	2 ± 4
Adjuvant irradiation*	24 (47)	21 (43)

Values are mean ± s.d. except where indicated (*). Percentages are given in parentheses

Results

The drainage volume for the exercise group was 15 per cent more than that for the immobilized group (379 *versus* 322 ml, *Table 2*). This difference approached statistical significance. Seromas developed more often in the exercise group but no significant difference was found in volume, duration or number of aspirations.

Four patients (8 per cent) from the exercise group and one (2 per cent) from the immobilized group exhibited delayed wound healing. Infections were seen only in the exercise group. In both groups there was one haemorrhage which required intervention.

Table 3 shows the limitation of shoulder function at discharge. A mean decrease in anteflexion of 7° and in abduction of 10° was noted for the exercise group, compared with about 10° for both functions in the immobilized group. These differences were not significant. The number of patients with a functional loss of more than 15° was slightly higher in the immobilized group.

Discussion

As the characteristics of the mastectomy wound predispose to seroma formation and shoulder dysfunction, every effort should be made to minimize these problems. Since the era of the Halsted radical mastectomy, much emphasis has been placed on the prevention of a frozen shoulder[2,3], but only a few studies have evaluated the risks and benefits of these exercises.

In two randomized prospective studies[4,5], shoulder immobilization for 7 days reduced the drainage volume significantly. However, after radical mastectomy this resulted in unacceptable shoulder dysfunction lasting 4 months[4]. In the

Table 2 *Total drainage volume, management of wound seromas and incidence of wound complications*

other study[5], no significant difference in shoulder function was noted when the exercise and immobilized group were compared 1 month after axillary dissection for melanoma or breast cancer.

In our study of modified radical mastectomy patients the period of immobilization was set at 5 days. As a result, preoperative shoulder function was achieved sooner than in the above-mentioned studies. Fourteen days after surgery no significant difference in function was observed.

In addition, there was a trend towards decreased drainage volume and a lower incidence of seroma formation in the immobilized group, which may represent an advantage of delayed shoulder exercises and merit continued study. As no adverse effect on shoulder function has been shown, routine shoulder exercises before the fifth postoperative day should be abandoned.

A simple specimen mount for the orientation of breast biopsies

P. G. Bentley

The Nuffield Hospital, Tunbridge Wells, Kent, UK

As a result of the wider use of screening mammography, surgeons are increasingly called on to excise impalpable lesions. Such specimens require postexcisional radiographs to confirm removal of the lesion and to guide the pathologist to the abnormal area, which may not be exactly at the tip of the localizing guide wire. Correct orientation of the specimen is essential and this paper describes a simple and inexpensive aid.

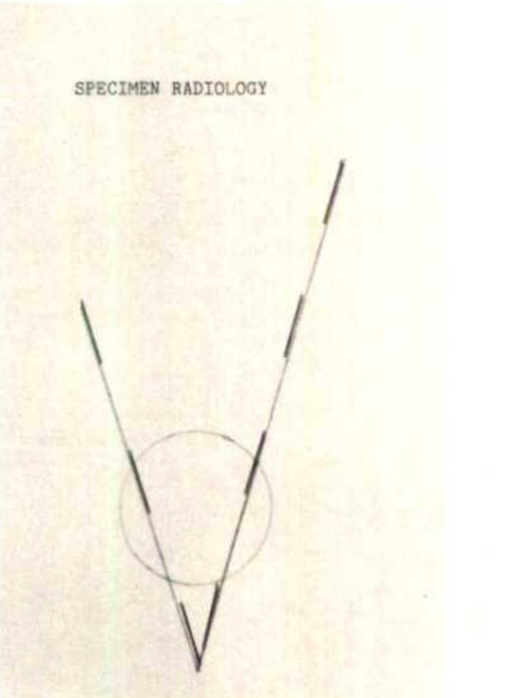

Figure 1 *White fibre-free card marked with staples in the form of a* V

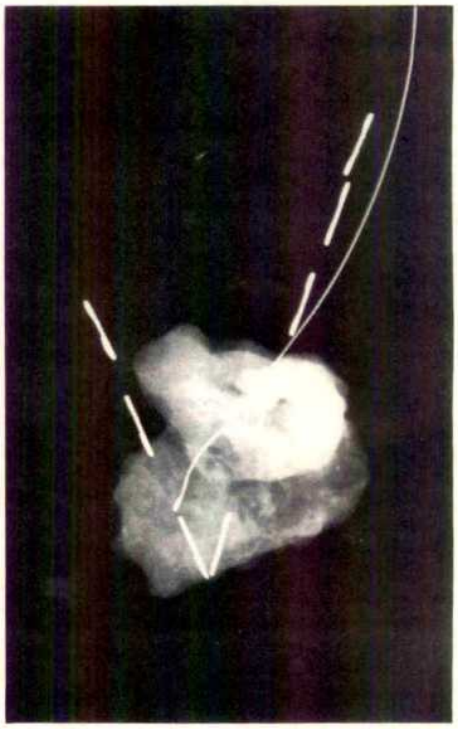

Figure 2 *The card and specimen are X-rayed to confirm that the abnormal area has been included*

A piece of white, fibre-free card is marked with staples in the form of a V with limbs of unequal length (*Figure 1*). The card and staples are then autoclaved and packed separately ready for use. Following hook-wire localization and surgical removal of the area of breast tissue, the specimen is placed on a card and sewn to it with a silk stitch at three sites around the periphery. The card and specimen are then X-rayed to confirm that the abnormal area has been included (*Figure 2*) and then the whole card and specimen are immersed in formalin and sent to the pathologist. The position of the lesion can then be found easily and multiple blocks taken of this area. The difference in length of the arms of the V ensures that the X-ray is not reversed.

Biliopancreatic bypass in the Prader–Willi syndrome

J.-J. Brossy

Department of Surgery, Victoria Hospital, Cape Town, South Africa

Correspondence to: Mr J.-J. Brossy, Department of Anatomy and Cell Biology, University of Cape Town Medical School, Observatory, 7925 Cape Town, South Africa

The Prader–Willi syndrome (PWS) is an uncommon childhood condition probably due to an abnormality of chromosome 15 (References 1 and 2). It presents as mental retardation, hypotonia, hypogonadism and obesity. Hyperphagia starts at the age of 2–3 years and within a decade the victims are grossly obese. The mental state makes dieting difficult and food theft is common. This provokes severe friction in the family.

Case report

A 31-year-old man showed the classic features of PWS. He was the eldest of three children; the two siblings were female and normal. His mental development was adequate to allow conversation but his comprehension was questionable. He goes to sheltered employment. His height is 163 cm and when first seen he weighed over 100 kg and became dyspnoeic on walking 50 m on level ground. His thighs and calves were huge and he had pitting oedema. He could eat anything which was offered him and never felt full. He was co-operative when the problem was discussed but in practice was unable to control the hyperphagia. The need to ration his food led to a highly emotional stress and he deeply resented his parents' attempts to control his intake.

On considering surgical management it was clear that gastric stapling would, if anything, aggravate the emotional issues so a biliopancreatic bypass[3] was proposed (*Figure 1*). This is a major operation and morbidity in obese patients includes infection, pulmonary complications and incisional hernia. Diarrhoea is seldom severe and nutritional deficiencies are uncommon. Except for the excised part of the stomach, the operation is reversible, although this is rarely needed.

The operation was discussed in detail with the patient and family. His blood biochemistry was carefully checked and he was prepared with a routine of exercises. The surgery was uneventful and at its termination the patient was able to breathe spontaneously so he was extubated. He was nursed in a sitting position, in a chair; a bed was avoided, even at night. In this position respiration is unhindered and assisted ambulation is much easier. Our patient did well, was home within a week and back at work in the third week.

Discussion

It is now established that hunger and satiety are both under the control of centres in the hypothalamus[4]. Owing to defects in one or both centres the PWS patient experiences no feeling of fullness. Dietary discipline takes enormous effort and is impossible to maintain. Soper *et al.*[5] performed gastric stapling in about 40 children including 7 with PWS but the results were disappointing: the very small capacity leads to overeating with nausea, vomiting, oesophagitis and peptic ulcer. A previous report of a jejunoileal shunt[6] with a successful outcome encouraged us to consider this option for our patient. Three years later he has lost 20 kg, can walk considerable distances, and eats more or less what he wants. His bowels work 2–4 times a day but he has good control. His blood parameters remain normal. He feels well and the tension and friction at home have disappeared. We believe that this operation should be considered in all PWS patients who survive to their teens.

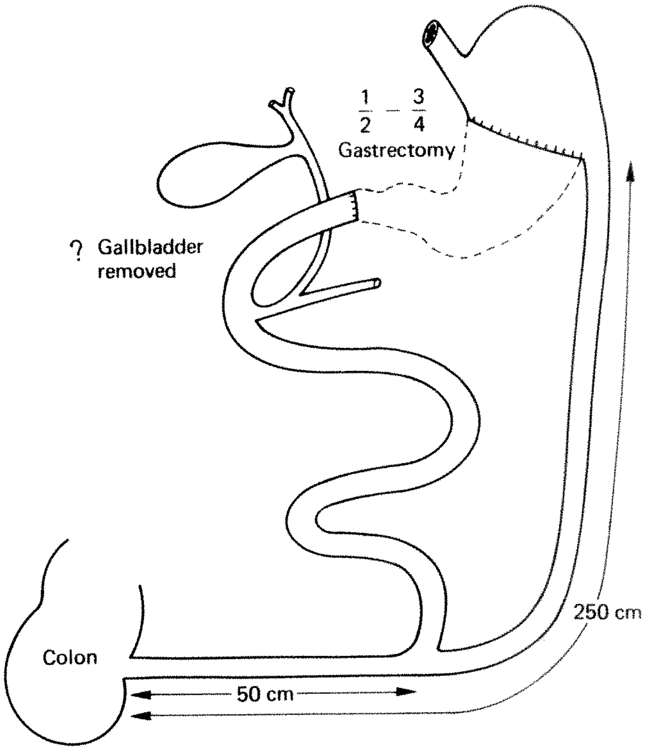

Figure 1 *Biliopancreatic bypass, after Scopinaro et al.*[3]*. The operation involves resecting about half of the stomach and closing the duodenum. The small intestine is then divided about two-thirds of the way down; the lower, ileal loop is taken up to the gastric remnant and the upper, jejunal loop is anastomosed to the lower loop 50 cm from the caecum, which thus becomes the only part of the gut where mixing of food with digestive juices and absorption can take place. It is effectively a very long Roux-en-Y loop*

Peritoneal lavage with mercuric chloride: toxic and unnecessary

J. S. Friedland and P. J. T. Vallance

Renal Unit, Guy's Hospital, St. Thomas Street, London SE1, UK

Correspondence to: Dr P. J. T. Vallance, Department of Pharmacology and Clinical Pharmacology, St. George's Hospital Medical School, London SW17 0RE, UK

Mercuric chloride is the most toxic of the inorganic mercury salts and can cause tissue corrosion, neurotoxicity, acute renal failure and circulatory collapse[1]. Mercuric chloride solutions are still used as topical anticancer agents in operations for colorectal carcinoma despite the known risk of precipitating acute renal failure and even death[2]. We report on a patient who developed severe mercury toxicity and who subsequently died following intraperitoneal instillation of mercuric chloride solution.

Case report

A previously fit 70-year-old man underwent uncomplicated right hemicolectomy for a Dukes' C adenocarcinoma. Within 24 h of surgery the patient had become severely unwell and anuric. Shortly afterwards he was transferred to the Intensive Therapy Unit at Guy's Hospital under the care of the Renal Unit. On examination he was confused, drowsy, dehydrated and had a coarse tremor of both hands. The pulse rate was 100 beats per min and blood pressure was 100/60 mmHg with a central venous pressure of $+3\,\mathrm{cmH_2O}$. On examination of the chest there was a right-sided pleural effusion. The abdomen was tender with widespread guarding and rebound tenderness maximal in the right lower quadrant. Serum urea and serum creatinine were raised at 17·6 mmol litre^{-1} (normal range 2·5–7·5 mmol litre^{-1}) and 590 μmol litre^{-1} (normal range 50–130 μmol litre^{-1}) respectively.

An intravenous infusion of colloid increased the central venous pressure to $+9\,\mathrm{cmH_2O}$, and the blood pressure to 150/65 mmHg. A dopamine infusion was started at 2·5 μg kg^{-1} min^{-1} and urine flow rates of over 100 ml h^{-1} were achieved. After extensive microbiological sampling, all of which was later found to be negative, broad-spectrum antibiotic therapy was instituted. The patient remained unwell requiring ventilation and intravenous feeding. In view of worsening abdominal signs he underwent repeat laparotomy. The anastomosis was found to be intact. However, there was marked erosion of the posterior abdominal wall with bloody, purulent fluid in the right paramedian, subhepatic and pelvic spaces.

Postoperatively the patient remained unwell with severe abdominal tenderness. At this stage, it was reported by the referring hospital that, before closure of the original wound, 50 ml of 1:500 mercuric chloride solution was instilled intraperitoneally. Forty-eight hours after the initial operation the blood mercury level was found to be 560 μg litre^{-1} (toxic range >50 μg litre^{-1}) and the urine level was 2700 μg litre^{-1}. Treatment was started with intravenous 2,3-dimercapto-1-propanesulphonate, a chelating agent which has been widely used in the USSR, and which is being evaluated for the treatment of mercury toxicity by the Poisons Unit at New Cross Hospital, London, UK. High levels of mercury clearance were achieved as renal function improved, with the serum creatinine falling to 293 μmol litre^{-1}. The patient was weaned from the ventilator and neurological function showed signs of improvement. However respiratory problems with recurrent large pleural effusions persisted and 8 days after admission the patient became asystolic. Attempts at resuscitation were unsuccessful. Post mortem revealed high levels of mercury in the liver (5950 μg kg^{-1}), the renal cortex (8800 μg kg^{-1}) and the renal medulla (7499 μg kg^{-1}).

Discussion

The clinical manifestations of acute inorganic mercury toxicity have been well described[1,2,4]. This patient developed severe local and systemic manifestations of mercury toxicity within 24 h of the intraperitoneal instillation of 50 ml of 1:500 mercuric chloride solution, and subsequently died following the development of pulmonary complications. The use of mercuric chloride solutions for peritoneal lavage was first reported to cause acute renal failure more than 20 years ago[2]. Subsequent reports of serious adverse effects, including five known deaths associated with its use, were reviewed as recently as 1984[2]. The efficacy of mercuric chloride as a local cancericidal agent has been questioned[2,5] and, while local irrigation of the bowel with 1:500 mercuric chloride solution may not be associated with toxicity, the practice of using the solution or similar ones for peritoneal lavage can no longer be justified and should now cease.

Acknowledgements

We should like to thank the Poisons Unit, New Cross Hospital, London, UK for providing mercury levels.

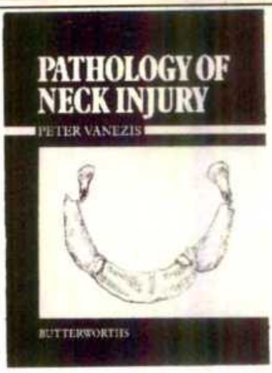
NEW FROM BUTTERWORTHS . . .

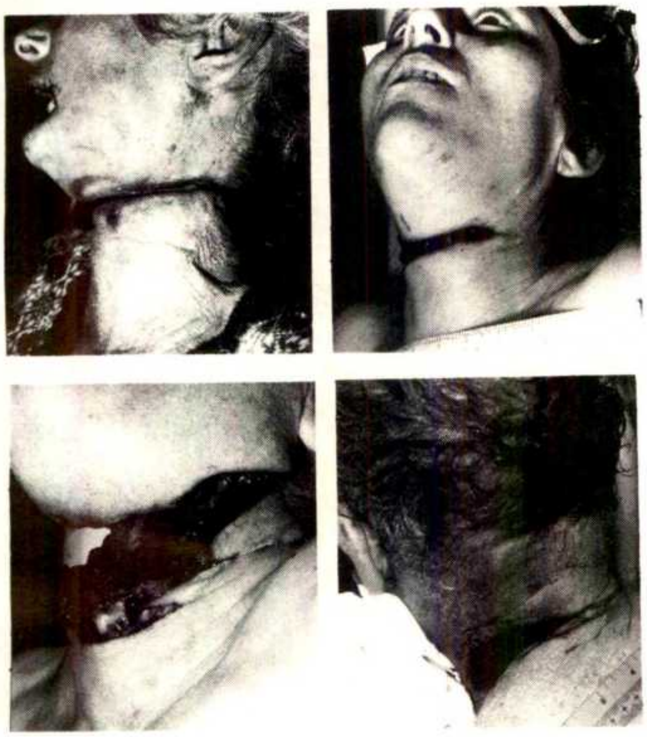
Pathology of Neck Injury

Peter Vanezis, MD, MRCPath, DMJ(Path)
Senior Lecturer in Forensic Medicine, Department of Forensic Medicine, The London Hospital Medical School, UK.

- ★ **a practical guide and general reference dealing with all pathological aspects of neck injury**
- ★ **of interest to everyone engaged in forensic work as well as pathologists and ENT surgeons**
- ★ **covers all aspects of injury in the neck region including the airways, trachea and larynx etc.**



In the clear and highly illustrated text, Peter Vanezis first explains the anatomy of the neck region and the various techniques required in its examination. He then describes penetrating injuries, comprising mainly sharp force trauma and firearm injuries. Asphyxial and related deaths are subsequently discussed in a series of five chapters before the author turns to the examination of blunt impact (non-compressive) injuries, and here special reference is made to their common occurrence in road traffic accidents. Finally, Dr Vanezis concerns himself with environmental, toxic and iatrogenic causes of injury.



Where appropriate, and especially with regard to penetrating and compressive modes of trauma, the interpretation of injuries and their differentiation into various categories such as homicidal, accidental or suicidal has been emphasized.

Pathology of Neck Injury is an essential guide for all those involved in the relevant specialties of pathology, surgery and forensic medicine.

Contents Introduction · Anatomy · Techniques of examination · Penetrating injuries · Compressive neck injury: I – Signs of mechanical asphyxia, II – Manual strangulation, III – Ligature strangulation, IV – Hanging · Internal airway obstruction · Non-compressive blunt impact injuries to the anterior compartment · Non-compressive blunt impact injuries to the posterior compartment · Toxic and miscellaneous environmental causes of neck injury · Injuries resulting from therapeutic, investigative and other related actions · Index

Essential Surgical Practice
Second Edition

★ Second edition of this classic systematic and comprehensive surgical textbook ★ Thoroughly revised and completely up-to-date ★ The section on cardiac surgery has been rewritten and to reflect its increasing importance there is a completely new section on the specialty of trauma surgery ★ Over 100 new illustrations ★ Comprehensively indexed ★ Many references for further reading

The second edition of this classic surgical textbook for postgraduate students has been thoroughly revised and updated to reflect the most recent advances and developments. The cardiac surgery section has been completely rewritten under new authorship and there is an entirely new section on trauma, rapidly emerging as a separate surgical specialty. All other chapters have been extensively revised or rewritten to bring them completely up-to-date.

Reviews of the First Edition

'This book is highly readable and is a real contribution to surgical education.' *Archives of Surgery*

'It should be a great success on both sides of the Atlantic.' *Annals of the Royal College of Surgeons*

'. . . Covers very well an extensive range of material which is well illustrated and readily comprehensive. It should be very useful equipment for the trainee surgeon for the Australasian college.'

Wound infection after appendicectomy

Sir

I read with great interest the review of wound infection after appendicectomy by Krukowski and colleagues (*Br J Surg* 1988; **75**: 1023–33).

The authors assume that the degree of operative contamination of the wound is one of the most important determinants of infection.

However, they state that 'quantitative bacteriology is laborious and has not been attempted in any clinical studies of wound infection after appendicectomy'.

This has been done recently in a study of 65 patients with perforated appendicitis[1]. During operation, the wound (and appendix) was sampled using velvet pads which were transported in an anaerobic atmosphere, shaken and rinsed, and cultured in an anaerobic cabinet.

In 15 patients who became infected, significantly higher densities of both aerobic and anaerobic bacteria were measured on the appendical surface and in the wound than in 50 patients who remained uninfected.

The median infective dose of bacteria (predominantly *Escherchia coli* and *Bacillus fragilis*) was $4{\cdot}6 \times 10^5$ c.f.u./cm^2 wound.

The study also demonstrated a high correlation between the density of wound bacteria and postoperative wound infection.

D. Raahave

University of Copenhagen
Anemonevej 24
Denmark

Author's reply

Sir

We regret having overlooked the important paper by Dr Raahave and his colleagues. They have clearly demonstrated the impact of operative contamination on the frequency of postoperative wound infection after appendicectomy.

We are concerned that a relevant paper should have escaped our notice and have reviewed again the 1986 and 1987 issues of *Index Medicus*. The paper is cited in the 1986 Author Index but does not appear in the 1986 or 1987 Subject Indices under any of the categories relating to the Appendix, although we have found it, in retrospect, under 'Bacteria, anaerobic/isolation and purification' and 'Surgical wound infection/microbiology'. Unfortunately the title did not alert us to its relevance to perforated appendicitis.

Wound instillation for postoperative pain relief

Sir

It is with great interest that we read the recent article by Gibbs *et al.* (*Br J Surg* 1988; **75**: 923–4) which did not demonstrate any difference between bupivacaine and saline in wound perfusion after cholecystectomy. Their results mirror those of our recently completed study.

Seventy patients having elective aortic surgery were randomized to receive either 40 ml 0·25 per cent bupivacaine or saline every 4 h for a total of 48 h into indwelling wound irrigation catheters. In transverse incisions two catheters were randomly placed either in the rectus sheath or subcutaneously; in vertical incisions one catheter was placed subcutaneously.

There was no significant difference in either pain scores, morphine requirements or parameters of pulmonary function between the saline ($n = 33$) and the bupivacaine ($n = 37$) groups. Siting of the catheters in the transverse groups made no difference. The mean pain score on the first postoperative day was lower ($P < 0{\cdot}05$) in patients with transverse ($n = 49$) than in those with vertical ($n = 21$) incisions.

Benign breast lump

Sir

The article by Sainsbury *et al.* (*Br J Surg* 1988; **75**: 1080–2) on the natural history of the benign breast lump is a worthy addition to a valuable series from their unit but cannot be allowed to pass without comment. Their case rests on a 100 per cent success rate in obtaining adequate biopsies and their faith in the predictive value of a benign report. Their series contained four carcinomas diagnosed on cytology but not clinically. This is consistent with the experience of Wilkinson and Forrest[1] who had a 6 per cent incidence of carcinoma in their series of 134 clinical fibroadenomas.

In our own series of 75 clinical fibroadenomas (discrete, well demarcated, smooth, mobile, painless breast masses) with cytological and histological diagnoses, there was a 5 per cent incidence of malignancy. The authors' performance in obtaining 100 per cent adequate biopsy rate is remarkable. In our own series biopsies were inadequate for diagnosis in 16 per cent of 51 proven fibroadenomas and 54 per cent of the other lesions, including one carcinoma. Cytological diagnosis of breast cancer is highly specific but by no means 100 per cent sensitive. Although the Newcastle group's performance in confirming benign disease (where clinical diagnosis is 95 per cent accurate) is enviable, the crux of their paper is the four cancer cases. Can they tell us how many repeat biopsies were necessary in this series, and whether the repeat biopsy rate was operator-dependent? Are they certain that they can achieve 100 per cent sensitivity in the diagnosis of breast cancer in these small mobile lesions? Does a series of four cases allow them to be sure that they will never be misled by a genuine benign report from a pathologist misled by a sampling error?

It comes as no surprise to breast surgeons to know that many benign lumps will resolve spontaneously (even though some would remain sceptical about the authors' ability to convince us that they can diagnose fibroadenoma accurately without histology). Using strict clinical criteria we can all accurately diagnose benign disease in young women in whom breast cancer is rare. Perhaps we need a larger series than this, with four cases, to prove that these rare cancers will not be missed, even occasionally, if a non-excisional policy is pursued by groups less skilled in cytological biopsy and diagnosis than Mr Sainsbury and his colleagues.

M. Burke

Harrow HA1 3UJ
UK

1. Wilkinson S, Forrest APM. Fibro-adenoma of the breast. *Br J Surg* 1985; **72**: 838–40.

Author's reply

Sir

Thank you for allowing me to see Mr Burke's letter and to comment. Mr Burke is right to point out that the crux of our paper is the four cancer cases. No repeat biopsies were needed to diagnose these four which were all found at their first visit to the clinic. Repeat biopsies were needed in this series in 17 per cent of cases. These were nearly all operator-dependent, having initially been carried out by the senior house officer who attends the clinic for training purposes. In these cases the repeat specimen was obtained by either the consultant or senior registrar. I think that both operator dependency and good cytopathological interpretation are vital. We are extremely fortunate in having an experienced pathologist whose initial, inclinic report is highly accurate[1]. We are quite aggressive with the needle cytology and a thorough biopsy of the area is obtained. I do not think we can ever be certain of 100 per cent sensitivity in diagnosis of breast cancer in the small mobile lesion but all four of the cancers were diagnosed at first visit.

I agree with Mr Burke's comment that a larger series is needed. I think one of the messages of our paper was that, given strict clinical and cytological criteria, not all breast lumps need excising in young women, given that an accurate cytological and clinical diagnosis has been made.

Endoscopic sphincterotomy

Sir

We read with interest the paper by Messrs Lambert, Martin and Tweedle (*Br J Surg* 1988; **75**: 896–8) which describes their experience of endoscopic sphincterotomy for retained bile duct stones. They reported a success rate of 86 per cent, a complication rate of 19 per cent (or 15 per cent if occult haemorrhages are excluded), and a mortality rate of 1·3 per cent, and understandably recommended that the technique should only be used when other non-operative treatments are inappropriate or have failed. However, they failed to point out that their results differed markedly from those of all previous reports on the subject[1–4]. Four previous reports (two of which were admittedly only small series) reported success rates of 95–100 per cent, complication rates of 0–8 per cent, and no deaths occurred. The collective results for 135 patients were a success rate of 96 per cent and a complication rate of 3 per cent. We have treated 32 patients (within 14 days of operation in 14 patients) and have achieved complete duct clearance in 28 (88 per cent) with a complication rate of 3 per cent (a single patient whose haemorrhage was treated conservatively).

We feel that these results compare favourably with those of other non-operative treatments and endoscopic sphincterotomy has the advantage of allowing the retained stones to be removed during the same admission. We no longer regard the discovery of retained stones with dismay and indeed there may be instances when it is safer to leave stones behind for later endoscopic removal rather than to risk damaging the bile duct by persistent attempts at operative removal.

Fine needle aspiration cytology

Sir

The conclusions of Nicholson *et al.* (*Br J Surg* 1988; **75**: 847–50) on the accuracy of fine needle aspiration cytology in breast disease appear to be unsound. Cytology was one of the determinants of excision and 'confirmatory' histology. Excision and histology were carried out only in a minority of patients with benign cytology and histology was also not available in elderly patients with malignant cytology. Surely the predictive accuracy of cytology can be reliably determined only by a blind comparison with histology; the assumption that patients without histology had benign disease (or malignant in the elderly) invalidates the analysis. If we overlook the elderly patients assumed (without histology) to have malignant disease, a false positive rate may be calculated, but none of the other predictions of the decision analysis (false negative rate, sensitivity, specificity and diagnostic accuracy) is valid since there is no histological information on which true negative and false negative cytology may be established. When the authors give figures of 96 per cent for diagnostic accuracy, 90 per cent for sensitivity and 99 per cent for specificity, they are also ignoring the high frequency of aspirates unsatisfactory for cytology (28 per cent), although this is a more minor criticism than that of the lack of histological information in the majority of their patients, which appears to invalidate their claims.

Author's reply

Sir

Thank you for allowing me to reply to Mr Matheson's comments about our paper 'Use of fine needle aspiration cytology with immediate reporting in the diagnosis of breast disease'.

The study did not set out to compare fine needle aspiration cytology (FNAC) with open biopsy. Its objectives were to compare the ability of FNAC to be used as a diagnostic method in the clinic, and measurements of sensitivity, specificity and accuracy were used to compare immediate reports (achieved in the clinic) with definitive reports, issued when all slides from each patient had been reviewed and a definitive cytological diagnosis achieved at a later time in the cytology laboratory. These points were emphasized: 'This study examines the feasibility and accuracy of FNAC in immediate reporting'. *Table 3* shows the comparisons between immediate and definitive cytology results and, similarly, our conclusions try to point out that 'there was no significant difference in any category between immediate and definitive reporting'.

Unsatisfactory cytology preparations were excluded from the final analysis because these were not acceptable as part of the clinical appraisal in these patients. A repeat aspirate would have been performed or other modalities would have been employed (clinical examination and follow-up with mammography) to achieve diagnosis. The main aim of using fine needle aspiration biopsy in the assessment of patients with breast disease is to limit excisional biopsy. Extended follow-up of patients in this study with cytologically proved benign breast disease has validated this action[1]. In elderly patients without 'confirmatory' excisional biopsy, very careful follow-up and assessment of response to primary endocrine therapy leaves little doubt as to the accuracy of fine needle biopsy[2].

The use of FNAC in breast disease is only slowly gaining acceptance. All studies which compare its accuracy with excisional biopsy show that this is a highly accurate technique. It has been shown to be more accurate than core needle biopsy.

We do not believe our claims go beyond the allowances of the data and analysis that we have presented.

Intragastric pH and duodenal ulcer

Sir

I read with interest the results of Rogers *et al.* (*Br J Surg* 1988; **75**: 961–5) concerning 24-h intragastric pH monitoring and would like to raise two points.

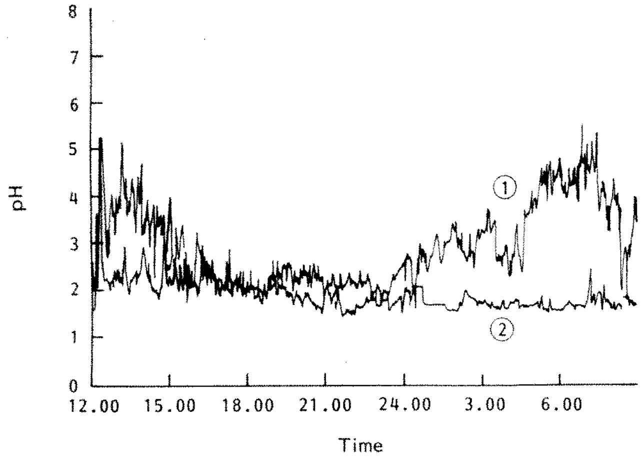

Figure 1 *Postoperative median pH curves of the group with ② and without ① ulcer recurrences, respectively*

The intraindividual day-to-day variation of 24-h intragastric pH monitoring cannot be proved by the median 24-h pH of 28 subjects on two separate occasions. Even if the values of this group were exactly the same on two separate occasions, this does not exclude the possibility that the median pH over the 24 h, or at least certain phases of it, might vary considerably on two different days in the individual[1].

The authors' conclusion from the measurements after highly selective vagotomy (HSV), suggesting a lesser importance of the suppression of nocturnal acidity for the healing of duodenal ulcers, is not based on convincing results. Rogers *et al.* have assumed that most of the 20 vagotomies (median night-time pH 1·7) had been 'complete' although three patients had a positive insulin test by Hollander's criteria and two patients had no test. Moreover, the predictive value of the insulin test is very poor due to its low sensitivity and specificity[2,3]. Before drawing such conclusions one would expect that the effect of vagotomy would be evaluated on a more reliable basis. The best criterion for evaluation of HSV is ulcer recurrence. We have compared the results of long-term intragastric pH monitoring in 42 patients without ulcer relapse and ten patients with ulcer recurrence after HSV (median time of follow-up, 3·9 years, range 2·4–6·1 years)[4,5]. The postoperative median 24-h pH of the group without recurrence was 2·7, which is similar to that in the report by Rogers *et al.*, but in patients with recurrence the pH was 1·9 (P=0·03). The most significant difference between both groups, however, could be found during the nocturnal period (from 20.00 hours to 06.00 hours): in patients with ulcer recurrence, the median pH was 1·7; for those without recurrence, the pH was 3·7 (P<0·01, *Figure 1*). Correspondingly, the most significant difference of the percentage of pH values lower than 2·0 between patients with and without recurrence, respectively, was found during the nocturnal phase (87 *versus* 20 per cent, P<0·001). A postoperative nocturnal median pH of < 2·0 was closely correlated with the occurrence of ulcer relapse. Our findings are in close accordance with the results of Gotthard *et al.* who have not been cited but who demonstrated in 1986 (with pH curves very similar to ours) that high nocturnal acidity is a predisposing factor for ulcer recurrence after HSV[6]. Hence, in accordance to Dragstedt's teaching, these facts support the view that suppression of nocturnal acidity is of crucial importance in the healing of duodenal ulcers.

Management of pelvic space

Sir

We read with interest the recent article by S. R. G. Smith *et al.* (*Br J Surg* 1988; **75**: 1012–5) regarding the management of the pelvic space following rectal excision. We shared their concern that pelvic drains may have a detrimental effect on rectal anastomoses and possibly lead to anastomotic dehiscence. We undertook four low anterior resections without drainage. Three of the four patients had major problems with anastomotic leakage and sepsis. This dramatic experience without drains has prompted the introduction of a 2 Redivac® (Biomet Ltd., Bridgend, UK) drainage regime with one leak in 19 subsequent cases. We place particular importance on the early activation of drainage during abdominal closure to prevent the early accumulation of clot in the pelvis.

We routinely mobilize the splenic flexure and appreciating the beneficial protective value of the omentum mobilize it from the colon and introduce it anteriorly into the pelvis and allow it to drape laterally around the anastomosis. We do not mobilize the omentum from the stomach and rarely have difficulty in obtaining sufficient omentum to fill the pelvis. The omentum is tethered in the upper abdomen by its attachment to the colon and, particularly, by its attachment to the splenic flexure.

Smith *et al.* have presented a series of patients which differ in the extent of resection. Our current feeling about the group of patients undergoing low anterior resection with total mesorectal excision is that pelvic drainage is necessary.

Tumour calcification after hepatic dearterialization

Sir

In response to the letter by our colleagues Messrs Charnley and Morris (*Br J Surg* 1988; **75**: 1150) we would like to add the following information. We were asked by the Editor to shorten our report, and several other reports on tumour calcifications following therapy were removed from the discussion. Calcifications in liver tumours are extremely rare. They are more common in primary liver cancer than metastatic disease[1]. In 1984 Schlanger and Wils[2] reported a patient in whom extensive tumour calcification had occurred in hepatic metastases from colonic cancer after hepatic artery infusion with 5-fluorouracil, Adriamycin® (Farmitalia Carlo Erba, St. Albans, UK) and mitomycin C. On publication this patient was alive and well after 28 months. In another study of ^{131}I antiferritin administration to patients with unresectable hepatomas, tumour calcification appeared in only those who responded to treatment[3]. The patient who survived the longest (3·5 years) without evidence of recurrent disease showed massive tumour calcifications. In the one study mentioned in our discussion, tumour calcification appeared concomitantly with a fall in carcinoembryonic antigen and a reduction of symptoms in a patient with hepatic metastases from *Pseudomyxoma peritonei* who was treated with intraperitoneal 5-fluorouracil[4].

There are thus several reports in the literature of tumour calcifications induced by different therapies appearing concomitantly with other signs of tumour regression.

In our discussion we state that the appearance of tumour calcification might be due to the combined effects of temporary dearterialization and intraperitoneal infusion of 5-fluorouracil. In a recently published article written by us, we did not register any tumour calcification following intraperitoneal administration of the same dose of 5-fluorouracil alone to a similar group of nine patients with colorectal liver metastases, and similar findings have been seen in a further 20 patients[5]. We think that it is more than merely a coincidence that tumour calcification appears in the first three patients treated with the addition of temporary dearterialization.

In our original manuscript six photographs of CT scans were included, showing all three patients. When Professor Anders Lunderquist reviews the floppy discs from the examinations and states that there is a regression of tumour growth in all three patients after institution of therapy, we believe him. We never judge tumour status from an individual X-ray photograph.

We do not claim any major benefit for the patients from this new treatment modality, but feel reassured by the appearance of some good prognostic signs to undertake a controlled clinical trial.

Parotid tumours

Sir

We read with great interest Gunn and Parrott's article entitled 'Parotid tumours: a review of parotid tumour surgery in the northern regional health authority 1978–1982' (*Br J Surg* 1988; **75**: 1144–6). The authors are to be congratulated on their exposé of the unsatisfactory way in which parotid tumours are currently managed. Unfortunately, we suspect that similar figures would be obtained from most health authorities if similar surveys were to be undertaken.

We are particularly concerned that this paper should not be used as an argument against formal parotidectomy, and wonder if the authors would agree with our suspicion that the high incidence of incomplete excisions following formal parotidectomy in this series (15·8 per cent) is a reflection of lack of experience on the part of the surgeon rather than a criticism of the operation itself (43·8 per cent of operations were performed by surgeons whose experience did not exceed an average of one parotid tumour case per year). Our own experience[1] demonstrates that, with experience, complete excision can be obtained in almost every patient (however thin the margin of normal tissue surrounding the tumour) and this implies that all patients with a lump in the parotid region should be referred to a centre with a particular interest and experience in such problems. Only with this focusing of the clinical material will surgeons in training obtain the necessary skills and sufficient experience to improve on the currently unsatisfactory situation described in the paper in question.

Since approximately 60 per cent of recurrences are multiple[2], the optimal time to cure the patient of a pleomorphic adenoma is at the first operation. Failure to do so increases the likelihood that the patient will ultimately suffer permanent facial palsy as parotidectomy for recurrent tumours carries a substantially increased risk of facial nerve damage. Moreover, as long as any residual tumour remains the greater must be the chance of malignant change.

Authors' reply

Sir

Thank you for showing us the letter by Professor Hobsley and Mr Watkins. We were pleased to note their interest in our paper and also noted their concern at the incidence of 15·8 per cent incomplete excisions for pleomorphic adenomas following formal parotidectomy. Whilst acknowledging the excellent results reported by Professor Hobsley, we still think that incomplete excisions will occur following conservative parotidectomy, particularly in tumours sited in the deep lobe, between the branches of the facial nerve or near the zygoma. All surgeons have 'learning curves' and even experienced surgeons will make mistakes. Similar reservations about complete excision of pleomorphic adenomas appear to be held by Conley[1].

Nevertheless, we agree that surgeons without a special interest in parotid surgery may wish to identify colleagues within their own, or other, districts to whom they would be happy to refer parotid tumours. It would seem that surgeons dealing with approximately from five to seven parotid tumours each year have a practice sufficient to produce good results[2].

Book reviews

Current Operative Surgery: Urology

A. R. Mundy. 192 × 260 mm. Pp. 217. Illustrated. 1988. London: Baillière Tindall. £42.50.

This multi-author compilation from world renowned specialists within urology is clearly yet concisely written and illustrated with top class line drawings and photographs. It is undoubtedly designed for trained urologists who wish to enlarge their repertoire of operative procedures, particularly those wishing to embark upon reconstructive lower tract or radical cancer surgery.

Each of the 12 chapters outlines the preoperative assessment, results and complications of a particular procedure and describes the intimate operative details that the readership will demand. Despite its basic premise as a practical manual, this volume serves as both a good tutor of relevant preoperative investigation and an excellent supervisor of the scientific literature germane to each technique. Its continuity of style and presentation also invites the reader to delve into those chapters which might not, at face value, excite the greatest immediate interest.

This volume serves to emphasize the need for continuing general training in urology by demonstrating that a variety of organ systems may benefit from 'conventional' surgery whilst underlining the need for specialist endoscopic expertise. It is to be thoroughly recommended to its intended audience.

Palliation in Malignant Disease

J. G. Mosley. 162 × 240 mm. Pp. 165. Illustrated. 1988. Edinburgh: Churchill Livingstone. £19.95.

Mr Mosley is to be congratulated on tackling this difficult subject with such a good reference background. The problem is that it is difficult to know who will read his work. He gives a subject-by-subject account of conventional treatment for various malignancies and then broad hints on how to manage the recurrent disease although not in as much detail as one would like. 'BCG vaccine, vaccinia virus or chemotherapy are useful palliative measures'—when and how often? As a reference for those who are not clinicians it may be helpful and if the library funds of a large district general hospital are flush perhaps this book may be justifiably purchased.
